(Dated: August 30, 2016)

We introduce a classification scheme for symmetry protected topological phases applicable to stationary states of open systems based on a generalization of the many-body polarization. The polarization can be used to probe the topological properties of non-interacting and interacting closed and open systems as well and remains a meaningful quantity even in the presence of moderate particle-number fluctuations. As examples, we discuss two open-system versions of a topological Thouless pump in the steady state of one-dimensional lattices driven by Markovian reservoirs. In the analogous unitary system, the Rice-Mele model, symmetries enforce topological properties which lead to a non-trivial winding of the geometric Zak phase upon cyclic variations of model parameters. Associated with this is a winding of the many-body polarization, corresponding to a quantized transport in the bulk (Thouless pump). We here show that in the open system, where the Zak phase looses its meaning, the same symmetries enforce a winding of the generalized many-body polarization. This winding is shown to be robust against Hamiltonian perturbations as well as homogeneous dephasing and particle losses.

Introduction.— Since the discovery of the quantum Hall effect [1] topological states of matter have fascinated scientists in all fields of physics. Topological phases can be characterized by non-local integer invariants [2], whose existence leads to a number of fascinating properties including protected edge states [3] and anyonic excitations [4]. Their robustness against disorder has made topological systems important tools in metrology and promising candidates for future quantum information platforms [5]. However, topological protection is typically destroyed by dissipation, e.g. decoherence or particle losses [6]. It would thus be highly desirable to extend the notion of topological order to open systems coupled to external reservoirs. This could even substantially extend topological protection since steady states are attractors of the dynamics and thus have an intrinsic robustness.

By now there is a rather good understanding of topological order in non-interacting closed systems. An exhaustive classification of gapped topological states of non-interacting fermions (the "ten-fold way" [7]) has been given solely on the basis of general symmetry properties. In contrast, the understanding of topological order in interacting systems [8] is limited and the extension to open systems is entirely in its infancy. Recently there have been some attempts to generalize the concept of topological order to steady states of open systems [9-11]. This includes proposals to extend Berry phases [12-14] to mixed states [15-18] e.g. using the Uhlmann phase [19], whose suitability has however been questioned [20]. Alternatives suggested for one-dimensional systems are based on projective symmetry group representations [21].

FIG. 1. (Color online) (a) Open-system analogue of the Rice-Mele model: One-dimensional fermion or spin chain with alternating pairwise coupling to two different Markovian reservoirs (Lindblad generators $L^A_j$ and $L^B_j$). The unit cell labeled by $j$ contains a left $L^L$ (blue) and a right $R^R$ (green) lattice site. (b) Winding of the many-body polarization in the fermionic model (see text) upon cyclic variations of parameters of the Liouvillian. On the axes with inversion symmetry (blue and green) the change in polarization is strictly quantized $\Delta P = 0, \pm 1/2$. On the special path along the periphery (red), the steady state is pure.

Here we pursue a different and more general approach, applicable also to interacting open systems. We consider the case where topology is protected by certain symmetries (symmetry protected topological order, SPT). A prime example of a unitary system with SPT is the Rice-
Mele model \cite{23}. The symmetries of the model enforce a non-trivial winding of the geometric Berry (or Zak) phase \cite{12, 13} upon cyclic variations of the parameters, which defines a topological invariant, the Chern number. As shown in \cite{14, 23, 29} the winding of the Zak phase is equivalent to a winding of the polarization, giving rise to a quantized particle transport known as Thouless pump \cite{2, 27, 29}. Such topological pumps are of special interest as they allow for studying the topological structure of parameter spaces \cite{30} and have been used to understand $Z_2$ topological insulators \cite{31}. Here we show that topological pumps can be used to classify SPT in the steady state of open, one-dimensional models. Specifically we consider open chains of fermions and spins with a Liouvillian dynamics obeying the same symmetries as the Rice-Mele model. We show that they enforce a non-trivial winding of the many-body polarization \cite{32}, characterizing a Thouless pump. While the Zak phase is no longer suitable to characterize topology, the winding of the polarization generalized to open systems with moderate particle number fluctuations defines a quantized topological invariant.

Classification scheme of SPT. — In the following we want to introduce our classification scheme, which generalizes the notion of SPT to open systems. It is motivated by the equivalence between the Zak phase and the many-body polarization \cite{25} formulated for periodic systems by Resta \cite{32} as

$$
P = \frac{1}{2\pi} \text{Im} \ln \left\langle \exp \left\{ \frac{2\pi}{L} \hat{X} \right\} \right\rangle ,$$

with $\hat{X}$ being the center of mass operator. This quantity has already been successfully applied to characterize quantized topological transport and SPT in one dimensional $L$-periodic closed systems \cite{14}. We here argue that this concept can be further generalized to periodic systems subject to dissipation.

In fact for this quantity to be meaningful the only restriction to be made is to fix the mean particle-number $\langle \hat{N} \rangle = L$ with non-extensive fluctuations, i.e. $\langle \Delta \hat{N} \rangle / \langle \hat{N} \rangle \rightarrow 0$ for all relevant states when $L \rightarrow \infty$. Under these conditions $P$, which is defined mod 1, is invariant under trivial changes of the particle coordinates by one unit cell in the limit $L \rightarrow \infty$. For half filling the system has furthermore particle-hole symmetry (PHS). We note that $P$ contains genuine many-particle contributions and is in general not determined by single-particle correlations alone.

We can now use eq.\,(1) to study systems with additional symmetries and a unique stationary state. Focusing concretely on spatial inversion (IS), we consider two inversion symmetric systems with polarizations $P_1$ and $P_2$. Because under inversion the difference of their polarizations $\Delta P = P_1 - P_2$ changes its sign $\Delta P \rightarrow -\Delta P$, but at the same time has to remain invariant because of IS, it follows that $\Delta P = -\Delta P \mod 1$. Therefore the difference $\Delta P$ can only take two quantized values $\Delta P = 0, 1/2$ \cite{13}. This quantization of the polarization has been heavily used in the context of closed periodic systems, e.g. in the Su-Schrieffer-Heeger (SSH) model \cite{33}, where the polarization can be directly related to the Zak phase \cite{25} and underlies the "ten-fold way" \cite{7}. We stress that this already makes it possible to classify SPT-phases in non-interacting and interacting closed and open systems as well.

In the following we demonstrate our method with two toy-models. We further prove that these systems can show a non-trivial winding number of the polarization on closed loops in parameter space, extending the concept of topological pumps to open systems.

Model. — We investigate driven-dissipative analogues of the translationally invariant Rice-Mele (RM) model \cite{23}. As indicated in Fig.\,(1b) we consider one-dimensional lattices of fermions and spins coupled to Markovian reservoirs described by Lindblad operators

$$
L^A_j = \sqrt{\Gamma(1+\varepsilon)} \left[ (1-\lambda) \left( \hat{A}_{L,j}^{\dagger} + \hat{A}_{R,j} \right) + (1+\lambda) \left( \hat{A}_{L,j} + \hat{A}_{R,j}^{\dagger} \right) \right] ,
$$

$$
L^B_j = \sqrt{\Gamma(1-\varepsilon)} \left[ (1-\lambda) \left( \hat{A}_{L,j+1}^{\dagger} + \hat{A}_{R,j} \right) + (1+\lambda) \left( \hat{A}_{L,j} + \hat{A}_{R,j+1}^{\dagger} \right) \right] .
$$

Each unit cell is defined and numbered by the index "$j$" and consists of two sites "$L$" and "$R$". $\hat{A}$ and $\hat{A}^{\dagger}$ denote fermion annihilation and creation operators, $\hat{c}$, $\hat{c}^{\dagger}$, (minus sign), or spin-operators $\hat{\sigma}^-$, $\hat{\sigma}^+$ (plus sign) respectively. $\Gamma$ is the coupling strength to the reservoirs and determines the overall time scale. Our model is characterized by two parameters $\lambda \in [-1,1]$ and $\varepsilon \in [-1,1]$, where $\varepsilon$ describes the relative strength of reservoir couplings across inequivalent links in the lattice and $\lambda$ controls the distribution of particles inside a unit cell. For $\lambda = 1$ ($\lambda = -1$) both Lindblad operators localize particles on the $L$-sites ($R$-sites). Despite their model character, there have been proposals for experimental realizations of reservoirs of similar structure using cold atoms \cite{9, 22, 24}.

We study the steady state $\rho_{ss}$ of the systems density matrix, which obeys the Master equation in Lindblad form ($\hbar = 1$) $\partial_t \rho_{ss} = \mathcal{L} \rho_{ss} = 0$, with

$$
\mathcal{L} \rho = -i[H, \rho] + \frac{1}{2} \sum_{\mu} (2L_{\mu} \rho L_{\mu}^{\dagger} - L_{\mu}^{\dagger}L_{\mu} \rho - \rho L_{\mu} L_{\mu}^{\dagger}) ,
$$

where $L_{\mu} \in \{L^A_j, L^B_j\}$. We consider periodic boundary conditions with $j = 1, \ldots, L$. To ensure a unique steady state for all parameters we introduce a potential, $H = U \sum_j \left( \hat{A}_{L,j}^{\dagger} \hat{A}_{L,j} + \hat{A}_{R,j}^{\dagger} \hat{A}_{R,j} \right)$ for fermions (+) or spins
\((-\) respectively and set \(U = \gamma\) for convenience. We further have to add non-linear modifications in the case of spins

\[
L_j^A \rightarrow L_j^A + \sqrt{1 + \varepsilon} \left( \hat{\sigma}_{L,j}^+ \hat{\sigma}_{R,j}^- - \hat{\sigma}_{L,j}^- \hat{\sigma}_{R,j}^+ \right), \quad (5)
\]

\[
L_j^B \rightarrow L_j^B + \sqrt{1 - \varepsilon} \left( \hat{\sigma}_{R,j}^+ \hat{\sigma}_{L,j}^- + \hat{\sigma}_{R,j}^- \hat{\sigma}_{L,j}^+ \right), \quad (6)
\]
in order to prevent the steady state from becoming completely mixed on the \(\lambda = 0\) axis (see supplementary material for details). We note that while the fermionic chain is gaussian, the spin chain is an example for a non-gaussian, i.e., an interacting system.

The following analysis relies on symmetries of the Lieb-Schultz-Mattis. Besides translation invariance by one unit cell, \(\mathcal{L}\) is invariant under \(C \cdot I_b\), i.e. simultaneous particle-hole exchange \((C)\) and spatial inversion with respect to any lattice bond \((I_b)\). As a consequence one finds that the average number of particles per unit cell is unity, \(\langle \hat{n}_{L,j} + \hat{n}_{R,j} \rangle = 1\), corresponding to half filling or PHS. As the steady state is unique, the change in polarization is well defined we find

\[
\langle \sigma_{L,j} \rangle = \langle \sigma_{R,j} \rangle = \frac{1}{2} \text{ for general parameter values on two-dimensional parameter space (}\varepsilon, \lambda\text{).}
\]

For the discussion of symmetry protected topological order we furthermore note that the system is invariant with respect to an inversion at a lattice site \((I_s)\) for \(\varepsilon = 0\) and with respect to a bond \((I_b)\) for \(\lambda = 0\).

**SPT and winding of polarization.**— We now show that the symmetries of the system enforce a non-trivial winding of the polarization upon a closed loop in the two dimensional parameter space \((\varepsilon, \lambda)\). To see this we note that \(\lambda \rightarrow -\lambda\) is equivalent to the action of \(C\), and \(\varepsilon \rightarrow -\varepsilon\) to \(I_s\). The most important consequence is that simultaneous transformation \((\lambda, \varepsilon) \rightarrow (-\lambda, -\varepsilon)\) is equivalent to a translation by one lattice site, i.e. \((L, j) \rightarrow (R, j)\) and \((R, j) \rightarrow (L, j + 1)\). Thus performing a point-inversion in parameter space, i.e. \((\lambda, \varepsilon) \rightarrow (-\lambda, -\varepsilon)\) leaves \(\mathcal{L}\) invariant up to a translation by one lattice site and if the polarization is well defined we find

\[
P(-\lambda, -\varepsilon) = P(\lambda, \varepsilon) \pm 1/2. \quad (7)
\]

As the steady state is unique, the change in polarization after one cycle has to be integer quantized, which, together with \((7)\) fixes the winding number of the polarization to \(\nu = \pm 1, \pm 3, \ldots\) This is confirmed by semi-analytical and numerical TEBD calculations for both types of chains, see Fig. 2(b).

Furthermore \((7)\) also results in the existence of two different SPT phases with a difference in polarization \(\Delta P = 1/2\) respectively for general parameter values on the \(\lambda = 0\)- or \(\varepsilon = 0\)-axis, see Fig. 2(b). Therefore a topological transition takes place in the center \(\lambda = \varepsilon = 0\), where \(P\) is not defined and \(\Delta P\) can change discontinuously.

**Pure steady states.**— It is interesting to consider the steady state for parameters along the special path in parameter space indicated in Fig. 2(b): (i) \(\varepsilon = 1, \lambda = 1 \rightarrow -1\), (ii) \(\lambda = -1, \varepsilon = 1 \rightarrow -1\), (iii) \(\varepsilon = -1, \lambda = -1 \rightarrow +1\), and finally (iv) \(\lambda = +1, \varepsilon = -1 \rightarrow 1\). Here a pure steady state \(\rho_{ss} = |\Psi\rangle\langle\Psi|\) exists. On (i) and (ii) it factorizes in unit cells \(\langle \Psi(\lambda) \rangle = \prod_j |\phi(\lambda)\rangle_j\), where up to normalization \(\langle \phi(\lambda) \rangle_j = (1 - \lambda)A^j_{L,j} |0\rangle + (1 + \lambda)A^{\dagger j}_{R,j} |0\rangle\). Here \(|0\rangle\) denotes \(\mid \downarrow_{L,j} \uparrow_{R,j}\) for spins and the vacuum for fermions. On parts (iii) and (iv) the steady state factorizes in new unit cells that are shifted by one site with respect to the old ones.

Because \(|\Psi\rangle\) is a pure steady state (dark state), it is the ground state of the parent Hamiltonian \(H_{\text{par}} = \sum_{\mu} L_{\mu}^+ L_{\mu} \geq 0\) which encodes all properties of the steady state. For our models with periodic boundary conditions the parent Hamiltonian reads \(H_{\text{par}} = H_{\text{RM}} + H_1\), where \(H_{\text{RM}}\) is the Rice-Mele Hamiltonian, describing the dynamics of fermions or spin excitations in a superlattice with alternating hopping matrix elements \(t_1 = 2\Gamma(1 + \varepsilon)(1 - \lambda^2)\) and \(t_2 = 2\Gamma(1 - \varepsilon)(1 - \lambda^2)\) and a staggered potential \(\pm \Delta\) with \(\Delta = 8\Gamma\). This model is a paradigmatic example for a topological Thouless pump \(27\). When following the systems ground state adiabatically while \(t_1 \rightarrow t_2\) and \(\Delta\) encircle the topological singularity at \(t_1 = t_2, \Delta = 0\), a quantized current is induced in the bulk. It can be associated with a quantized winding of the many-body polarization, corresponding to an integer topological Chern number \((C = 1)\). The second term \(H_1\) has no effect on the dark state since \(H_1 |\Psi(\lambda)\rangle = 0\).

**Robustness.**— In closed systems topological properties are known to be robust against perturbations that do not close the energy gap. This makes it interesting to ask whether the winding of the polarization in an open system can be robust against Hamiltonian and Liouvillian perturbations.

For the spin chain we evolved the stationary state numerically, employing the time-dependent block decima-
tion (TEBD)\textsuperscript{34} to investigate robustness in sufficiently large systems ($L = 16$) along a circular path as indicated in Fig.2a).

For the fermionic chain, which is linear in fermionic operators, we can calculate the polarization of its steady state semi-analytically\textsuperscript{34}. However because we add perturbations that are non-linear in fermionic operators like dephasing or spatial randomness, we can only check for robustness in small periodic systems of four sites. This is sufficient because topological effects should not depend on system size.

Specifically we analyzed three different types of perturbations which preserve the PHS of the steady state: (i) a spatially random magnetic field in the $z$-direction with uniform distribution, (ii) dephasing, and (iii) additional local losses compensated by local pumps with equal rates. In the first case we add a Hamiltonian

$$H_{\text{pert}} = \sum_{\mu} V w_{\mu} \left(1 - 2A_{\mu}^\dagger A_{\mu}\right),$$

where $\mu$ denotes a lattice site and $w_{\mu} \in [-1,1]$ are independent random magnetic field strengths. As can be seen from Fig.2b this perturbation has negligible influence on the polarization and does not affect its winding. In the second case we add an additional Lindblad term with $L_{\text{deph}}^{R/L,\mu} = \sqrt{\gamma_{\parallel}} \left(1 - 2A_{L/R,\mu}^\dagger A_{L/R,\mu}\right)$, where $\gamma_{\parallel}$ is the dephasing rate. This term, too, has almost no effect on $P$ and does not change its winding. The same is true for homogeneous losses and gain. These have to be added with equal rates $\gamma_{\parallel}$ however in order to maintain the PHS of the system, i.e. $\langle \hat{n}_L + \hat{n}_R \rangle = 1$: $L_{\text{deph}}^{R/L,\mu} = \sqrt{\gamma_{\parallel}} A_{L/R,\mu}^\dagger$, and $L_{\text{deph}}^{R/L,\mu} = \sqrt{\gamma_{\parallel}} A_{L/R,\mu}^\dagger$. The small effects of these non-hermitian perturbations are shown in Fig.2c).

Most interestingly $\Delta P = \pm 1/2$ between two inversion-symmetric points on the $\lambda = 0$ axis remains intact even in the presence of spatially homogeneous losses (see Fig.2c)). These findings are important, because they show that in an open system topological properties such as the quantized charge pump can be maintained even in the presence of unwanted losses, if the system remains PHS.

**Topological singularity.**— For open gaussian systems it has been argued in\textsuperscript{22} that a topological singularity, at which a topological phase transitions takes place, is connected to the closing of at least one of the two, the damping gap or the so-called purity gap. The damping gap is determined by the real part of the eigenvalues of $\mathcal{L}$, $\mathcal{L} \rho_s = \epsilon \rho_s$, which characterize the relaxation rate of the system. The steady state is a right eigenstate of $\mathcal{L}$ with eigenvalue $\epsilon = 0$ and the damping gap $\Delta_d$ is the distance to the next larger value of $\text{Re} \{\epsilon\}$. The purity gap of fermionic systems is determined by the eigenvalue spectrum of the positive semidefinite matrix $\left(i \gamma \right)^2$, where $\gamma$ is the antisymmetric and real steady state single-particle correlation matrix\textsuperscript{22}.

The damping gap is difficult to obtain from TEBD simulations and we have performed exact simulations for a four-site problem for the fermionic and non-linear spin chains. While even for such small system sizes we can already observe a quantized winding of the polarization, the damping gap is sizable everywhere (see supplementary material for details).

For the fermion model, which is gaussian, the purity gap is shown in Fig.3a. One recognizes a closing of the purity gap at the origin ($\lambda = \varepsilon = 0$) consistent with the behavior of the polarization. This suggests that our classification is in agreement with previous schemes for gaussian systems such as in\textsuperscript{22}. Since the spin system cannot be mapped to a free fermionic model the concept of the purity gap cannot be applied here. However for small systems with four sites we can evaluate the eigenvalue spectrum of the full density matrix. We find that the two dominant eigenvalues of $\rho_{ss}$ never become equal (see Fig.3b)). Although these calculations can only be done for finite systems this indicates that there is no closing of a ”generalized” purity gap since an indicator of a topological transition is expected to be independent of system size. Thus the conditions for a topological singularity and its nature in a dissipative system remain open questions devoted to further studies.

**Summary.**— To summarize, we have generalized the notion of SPT to steady states of one-dimensional interacting open systems. While topological invariants based on geometric phases such as the Zak phase known from closed systems are no longer applicable here, the quantized bulk transport of the Thouless pump remains a suitable indicator of topology in more general one-dimensional open systems and the winding of the polarization defines a topological invariant. The polarization is a measurable quantity even in an open system and specific detection protocols will be discussed in detail elsewhere\textsuperscript{37}.

As specific examples we investigated an open fermion and spin chain with reservoir couplings that lead to particle-hole symmetric steady states. We showed that

![FIG. 3.](image-url) (Color online) (a) purity spectrum of fermionic model. (b) Dominant values of the spectrum $\sigma(\rho_{ss})$ of the steady-state density matrix of the spin model for additional homogeneous dephasing $\gamma_{\perp} = 0.5 \Gamma$ at $\varepsilon = 0$ obtained from exact diagonalization of a four-site problem.)
the symmetries of the models enforce a non-trivial quantized winding of the many-body polarization upon cyclic parameter variations which characterizes a topological Thouless pump. In the presence of inversion symmetry distinct phases with quantized values of the many-body polarization emerge which defines symmetry protected topological order. We have shown that the polarization winding is robust to Hamiltonian disorder as well as to additional dephasing or moderate particle losses.

The conditions for a topological singularity remain an open question which requires further investigation. An interesting future avenue is the extension to higher spatial dimensions which may provide a way to realize topologically protected transport in an open system that is robust against particle losses.

SUPPLEMENTARY

Numerical method. — Aside from the special path, as seen in Fig.1 b) (main text), efficient numerical methods are needed to get insight into the dynamics of large systems. For this purpose we utilize an extension of the time-evolving-block-decimation algorithm (TEBD)\cite{34}. This method was originally conceived for efficient unitary time evolution of pure states in closed system and relies on the controlled truncation of the underlying Hilbert space, which is feasible for all moderately entangled states. Using small modifications however, the TEBD-algorithm can be easily extended to time evolution of mixed states in open systems. For this we embed the mixed state as a pure state in a larger Hilbert space, the so-called Liouville space using the isomorphism

\[ \rho = \sum_{\alpha,\beta} \rho_{\alpha,\beta} |\alpha\rangle\langle\beta| \leftrightarrow \sum_{\alpha,\beta} \rho_{\alpha,\beta} |\alpha\rangle |\beta\rangle \equiv |\rho\rangle, \]

The state now evolves under the Schrödinger-like equation

\[ \partial_t |\rho\rangle = \mathcal{L}|\rho\rangle, \]

with \( \mathcal{L} \) being the representation of \( \mathcal{L} \) in Liouville space.

Our results are obtained in large systems (L=16) with open boundary conditions. To minimize finite size effects Eq.\([1]\) is evaluated within a region inside the bulk of the system (L=14) resulting in a small error because per definition periodic boundaries are required and correlations between the edges are neglected. However this error is suppressed with increasing system size and vanishes in the thermodynamic limit as in our system spin-spin correlations decay exponentially on a length scale of one lattice site.

Necessity of non-linear modification. — On the whole \( \lambda = 0 \)-axis Lindblad generators \((2)\) and \((3)\) become hermitian. Thus \([L_\mu, L_\mu^\dagger] = 0\) holds and the completely mixed state

\[ \rho_M = \bigotimes_j \frac{1}{2} (|\uparrow\rangle\langle\uparrow| + |\downarrow\rangle\langle\downarrow|) \]

is a steady state of the system. In fact one can easily show that for this state Eq.\([1]\) is not defined as the argument of the logarithm becomes zero. To prevent a completely mixed steady state on the \( \lambda = 0 \) axis we add non-linear terms \((5)\) and \((6)\) to the original model.

Damping gap. — Although not attainable by TEBD, we can calculate the exact damping spectrum of a small four-site spin chain, as can be seen in Fig.4. In order to consider a most general case, while a quantized winding of the polarization is still observable, we include an additional dephasing. As can be seen from Fig.4 there is always a finite damping gap.

FIG. 4. (Color online) Two lowest eigenvalues of \( \mathcal{L} \) as function of reservoir parameters \( \lambda \) and \( \varepsilon \) with dephasing \( \gamma_\perp = 0.5\Gamma \). One finds no closure of the damping gap.
