(Dated: March 29, 2022)

The current-induced magnetization dynamics of a spin valve are studied using a macrospin (single domain) approximation and numerical solutions of a generalized Landau-Lifshitz-Gilbert equation. For the purpose of quantitative comparison with experiment [Kiselev et al. Nature 425, 380 (2003)], we calculate the resistance and microwave power as a function of current and external field including the effects of anisotropies, damping, spin-transfer torque, thermal fluctuations, spin-pumping, and incomplete absorption of transverse spin current. While many features of experiment appear in the simulations, there are two significant discrepancies: the current dependence of the precession frequency and the presence/absence of a microwave quiet magnetic phase with a distinct magnetoresistance signature. Comparison is made with micromagnetic simulations designed to model the same experiment.

I. INTRODUCTION

In the ten years since Slonczewski and Berger discovered the quantum mechanical phenomenon of spin-transfer torque, considerable evidence has accumulated that a spin-polarized current that passes through a thin ferromagnetic film can induce switching and/or precession of the film’s magnetization. Early experiments used multilayers, nanowires, small particle junctions, and point contacts to infer the presence of this effect. The most convincing data came later from pillar-type “spin valves” with nanometer-scale transverse dimensions (Fig. 1) where a thin film non-magnet is sandwiched between two thin film ferromagnets. In the range of film thicknesses most commonly used, the magnetization \( \mathbf{M} \) of the thick “fixed” layer and the magnetization \( \mathbf{m} \) of the thin “free” layer lie in the plane of the film. Nonmagnetic leads connect the spin valve to electron reservoirs.

Due to the phenomenon of giant magnetoresistance, voltage measurements are sufficient to reveal that hysteretic switching of \( \mathbf{m} \) occurs as a function of the applied current density \( J \) when a magnetic field \( H \) smaller than the coercive field is applied along the easy axis of the free layer. For larger values of \( H \), it is believed that \( \mathbf{m} \) exhibits one or more types of stable precession as a function of \( J \) until the current density is large enough to induce switching. This conclusion is based on the experimental observation of narrow band microwave emission combined with calculations using a generalized Landau-Lifshitz-Gilbert (LLG) equation that predict precession of the free layer. Other observed dynamical behavior includes telegraph noise that is interpreted as rapid switching between two distinct states of magnetization.

Several experimental groups have used the macrospin (single domain) approximation to propose “phase diagrams” that identify the dynamical state of their spin valves as a function of \( J \) and \( H \). These indicate that a spin-polarized current can induce switching and/or precession of the film’s magnetization. Early experiments have also been purely theoretical studies of the LLG equation (generalized to include spin-transfer torque) using both macrospin models and micromagnetic simulations that do not make the single-domain approximation. Unfortunately, it is difficult to extract a coherent picture from all this work because different authors make different choices for the physical effects they believe most affect the dynamics. There is not even unanimity amongst authors for the form of the spin-transfer torque itself.

This state of affairs motivated us to perform a thorough study of the LLG dynamics of a model spin-valve for the purpose of a quantitative comparison with the data reported by Kiselev et al. for a Co/Cu/Co nanopillar. We make the macrospin approximation, but otherwise systematically examine the effects of different forms of spin-transfer torque, thermal fluctuations, spin-pumping, incomplete absorption of transverse spin current, and angle-dependent damping. We find that a “minimal” macrospin model can reproduce many (but not all) features of the experiment. The most important points of disagreement are the current dependence of the precession frequency and the existence of a microwave quiet magnetic phase with a distinct magnetoresistance signature. In light of these results, we comment on micromagnetics.
The plan of this paper is as follows. Section II describes the macrospin models of interest and the generalized Landau-Lifshitz-Gilbert equation we solve numerically. Section III presents results for a “minimal” model and compares them to the measurements reported in Ref. 11. Section IV examines several variations of the minimal model within the context of the macrospin approximation. Section V compares our results with microscopic simulations. Section VI summarizes our results vis-à-vis experiment. An Appendix provides some details omitted from the main body of the paper.

II. THE MACROSPIN MODEL

Our macrospin model of the spin valve shown in Fig. 1 assumes that the magnetization is spatially uniform in both ferromagnetic layers with saturation value $M_s$. The fixed layer magnetization is $\mathbf{M} = M_s \mathbf{z}$, but we allow the unit vector in the direction of the free layer magnetization $\mathbf{m} = \mathbf{m} / M_s$ to point in any direction. In the coordinate system used here (Fig. 2),

$$\mathbf{m} = \hat{x} \sin \theta \cos \phi + \hat{y} \sin \theta \sin \phi + \hat{z} \cos \theta.$$ (1)

The experiments of interest use a “free” ferromagnetic layer with a thickness $d \approx 3$ nm and an elliptical shape of dimensions about $130 \times 70$ nm. Under these conditions, magnetostatic shape anisotropy makes the $y$-$z$ plane an easy plane for $\mathbf{m}$. The $z$-axis is an easy axis in that plane. The control parameters are an external magnetic field $H$ directed along $+z$ and an electric current $J$ that is reckoned positive when negatively charged electrons flow from $+x$ to $-x$.

We describe the dynamics of $\mathbf{m}$ using a generalized Landau-Lifshitz-Gilbert (LLG) equation,

$$\frac{d\mathbf{m}}{dt} = -\gamma \mathbf{m} \times \left[ H_{\text{eff}} + \mathbf{H}_T \right] + \alpha \mathbf{m} \times \frac{d\mathbf{m}}{dt} + \frac{\gamma}{\mu_0 M_s} \mathbf{N}. $$ (2)

The first term on the right side of Eq. (2) is a conventional magnetic torque with gyromagnetic ratio $\gamma$. This torque is driven by an effective field derived from the total energy $E$ of the free layer with volume $V$:

$$\mu_0 H_{\text{eff}} = -\frac{1}{V} \frac{\partial E}{\partial \mathbf{m}}.$$ (3)

Taking account of magnetostatics, the external field, and a uniaxial surface anisotropy, we show in Appendix I that $E$ can be written in the form

$$\frac{2E}{\mu_0 M_s^2 V} = h_Z \cos^2 \theta + h_Y \sin^2 \theta \sin^2 \phi + h_X \sin^2 \theta \cos^2 \phi - 2h \cos \theta.$$ (4)

Here, $h = H/M_s$ and the constants $h_X$, $h_Y$, and $h_Z$ are computed in Appendix I using the free layer data given just below Eq. (1) and the material constants listed in Table I.

B. Damping

The “Gilbert damping” term $\alpha \mathbf{m} \times \dot{\mathbf{m}}$ in Eq. (2) takes account of energy dissipation mechanisms such as coupling to lattice vibrations and spin-flip scattering. The prefactor $\alpha$ is usually treated as a phenomenological constant (Table I) although it is not known whether this is a good approximation for situations where the amplitude of precessional motion is large. The Landau-Lifshitz approach to damping replaces the Gilbert term in Eq. (2) by

$$\lambda \mathbf{m} \times (\dot{\mathbf{m}} \times \mathbf{H}_{\text{eff}}).$$ (5)

The constant $\lambda$ can be calculated in some microscopic models, but a phenomenological treatment is almost universal. When $\mathbf{N} = 0$ in Eq. (2), the Gilbert and Landau-Lifshitz expressions for the damping torque are known to be equivalent, at least formally. Section II.D gives a reason why we prefer the Gilbert form, but we performed calculations using both forms for purposes of comparison. No significant differences were found.

C. Thermal Fluctuations

The stochastic vector $\mathbf{H}_T$ in Eq. (2) is used to simulate the effect of finite temperature. Each Cartesian component is chosen at random from a normal distribution with a variance chosen so the system relaxes to a Boltzmann distribution at equilibrium. Specifically,

$$\langle H_{ij}^2(t) H_{ij}^2(t') \rangle = \frac{2k_B T \alpha}{\gamma V \mu_0 M_s} \delta_{ij} \delta(t - t'),$$ (6)
where $i, j = x, y, z$. We have confirmed numerically that this procedure does indeed produce a Boltzmann distribution of energies at temperature $T$ when $N = 0$ in Eq. (2). Details of our implementation of the stochastic contributions are indicated in Sec. III A.

D. Spin-Transfer

The quantity $N$ in Eq. (2) stands for one of several torque densities that arise from microscopic considerations of the transport of electrons through a spin valve. The most important of these is the spin-transfer torque density $N_{st}$, a variety of theoretical methods confirm the following picture. The current that flows through the spin valve shown in Fig. 1 is spin-polarized. Because $M$ and $\mathbf{m}$ are not collinear, the conduction electron spins that encounter the free layer generally possesses a component of angular momentum that is transverse to the magnetization of free layer itself. Realistic calculations show that this transverse component of angular momentum is largely absorbed by the ferromagnet. Since we describe the free layer as a uniformly magnetized particle, the absorbed angular momentum generates a torque that appears on the right hand side of Eq. (2). According to current theory, we have confirmed numerically that $N_{st}$ does not produce an effective field

$$N_{st} = \eta(\theta) \frac{\hbar}{2e\alpha} \mathbf{m} \times [\mathbf{m} \times \mathbf{M}], \quad (7)$$

where $\mathbf{M} = M/M_s$ and $\cos \theta = \mathbf{m} \cdot \mathbf{M}$.

The different forms of spin-transfer torque one finds in the literature reflect different choices for $\eta(\theta)$. If one simply puts $\eta(\theta) = \eta_0$, the result is a “sine” approximation to the torque, which is the remaining angular factors in Eq. (7) give $N_{st} \propto \sin \theta$ (Fig. 3). This form of the torque arises when there is spin-dependent scattering at the free layer interface and the polarization of the electron current that flows from the fixed layer to the free layer is independent of the orientation of the fixed layer. The prefactor $\eta(\theta)$ is not constant if there is a diffusive component to the current anywhere and/or spin-dependent reflection occurs at the fixed-layer interface. To our knowledge, one or both of these effects is present in all transport theory calculations of $N_{st}$. On the other hand, the corresponding $\sin^2(\theta/2)$ approximation for the angular dependence of the magnetoresistance describes real spin valve data better than one would expect based on the transport theory predictions, to which we will turn next.

Building on his original work, Slonczewski applied an approximate form of magneto-electronic circuit theory to a spin valve with equal lead lengths and equal ferromagnetic layer thicknesses. He found

$$\eta(\theta) = \frac{q}{A + B \cos \theta}, \quad \eta(\theta) = \frac{q_+}{A + B \cos \theta} + \frac{q_-}{A - B \cos \theta}, \quad (9)$$

where $q, A,$ and $B$ are material and geometric parameters. We will call this the symmetric Slonczewski (SS) approximation for the torque. For a general spin valve geometry, it turns out that

The present authors have shown that Eq. (9) gives quantitative agreement with calculations of the spin-transfer torque based on the Boltzmann transport equation for a wide variety of spin valve geometries. We will call this the asymmetric Slonczewski (AS) approximation. One of the solid curves in Fig. 3 shows that the symmetric and asymmetric Slonczewski torques are essentially identical for the particular spin valve geometry we use to model the experimental sample of Ref. 11 (see Sec. III). The two dashed curves show the difference between the the symmetric and asymmetric Slonczewski torques for a spin valve geometry we will discuss in Sec. VIB.

Spin-transfer torque accounts for non-equilibrium processes that cannot be described by an energy functional. This means that $N_{st}$ does not produce an effective field.

| Quantity | Values |
|----------|--------|
| $M_s$    | $0.127 \times 10^7$ A/m [11] |
| $\mu_0 M_s$ | 1.6 T |
| $\gamma$(Co) | $2.4 \times 10^5$ m/(A-s) [45] |
| $\alpha$(Co) | 0.01 [46] |
| $K_u$   | $0.5 \times 10^{-3}$ J/m$^2$ [47] |
| $g^u/S$(Cu) | $2.94 \times 10^{19}$ m$^{-2}$ [48] |
| $\nu$(Co/Cu) | 0.98 [48] |

TABLE I: Quantity Values
like Eq. (4) and no damping of spin-transfer dynamics occurs if $H_{\text{eff}} = 0$ and the Landau-Lifshitz form Eq. (7) is used for damping. On the other hand, if one believes that it must be possible to influence spin-transfer driven motion by transferring energy to other degrees of freedom, it is necessary to use the Gilbert form of damping in the magnetization equation of motion. This is what we do in Eq. (2).

E. Current-Induced Effective Field

First principles calculations\textsuperscript{50,51} show that the absorption of a transverse spin current at a ferromagnetic interface is not 100% efficient. Part of the fraction that survives gives a small correction to $\eta(\theta)$ in Eq. (7). The remainder is polarized perpendicular to both $\mathbf{m}$ and contributes a torque density on the free layer of the form

$$N_{\text{eff}} = \eta(\theta)\beta \frac{h}{2e d} J \hat{\mathbf{m}} \times \dot{\mathbf{M}}.$$  \hspace{1cm} (10)

In the circuit theory language of Brataas et al.\textsuperscript{60} this term is described by the imaginary part of the mixing conductance. Evidently, $N_{\text{eff}}$ produces motion of $\hat{\mathbf{m}}$ identical to that produced by an effective external field oriented along the magnetization direction $\mathbf{M}$ of the fixed layer. This contribution is usually neglected because the cited calculations find $\beta \approx 0.05$. We include it here because at least one experiment\textsuperscript{22} has been interpreted as demonstrating that $\beta \approx 0.20$.

F. Spin Pumping

A final contribution to the torque on the free layer comes from a phenomenon called “spin pumping”. Since a spin polarized current incident from a non-magnet can produce magnetization dynamics in an adjacent ferromagnet, it is not unreasonable that motion of the magnetization of a ferromagnet can influence the spin current in an adjacent non-magnet. The most prominent effect is the injection of a spin current into the non-magnet whenever the magnetization moves. One consequence of the injected spin current is a back-reaction torque that increases the damping of the spin motion.\textsuperscript{61,62,63} This effect has been confirmed by experiments.\textsuperscript{64,65,66,67} The torque density due to spin-pumping is given by Tserkovnyak et al.\textsuperscript{68} as

$$N_{\text{sp}} = \frac{1}{d} \hat{\mathbf{m}} \times J_{s}^{\text{exch}} \times \dot{\mathbf{m}},$$  \hspace{1cm} (11)

where

$$J_{s}^{\text{exch}} = \frac{1}{2} \left[ J_{s}^{\text{sp}} - \nu (J_{s}^{\text{sp}} \cdot \dot{\mathbf{M}}) \frac{\hat{\mathbf{M}} - \nu \hat{\mathbf{m}} \cos \theta}{1 - \nu^2 \cos^2 \theta} \right].$$  \hspace{1cm} (12)

with

$$J_{s}^{\text{sp}} = \frac{\hbar g_{\uparrow\downarrow}}{4\pi S} \hat{\mathbf{m}} \times \frac{d\hat{\mathbf{m}}}{dt}.$$  \hspace{1cm} (13)

$S$ is the cross-sectional area of the free layer. Table I gives numerical values for the parameters $\nu$ and $g_{\uparrow\downarrow}$ (defined in Ref. 68) for the Co/Cu/Co spin valve of interest to us here.

III. MINIMAL MODEL

This section compares LLG simulation results with the experimental results reported in Ref. 11. Our “minimal” model is Eq. (2) with $N = N_{\text{eff}}$ from Eq. (7) and the asymmetric Slonczewski (AS) choice in Eq. (9) for $\eta(\theta)$. This model takes account of magnetostatic and surface anisotropy, an external magnetic field, current-induced spin-transfer torque, Gilbert damping, and thermal fluctuations. Most of our calculations use a spin valve geometry (see Fig. 1) designed to mimic the nanopillar samples studied by Kiselev et al.\textsuperscript{54}

Cu(80 nm)/Co(40 nm)/Cu(thin)/Co(3 nm)/Cu(10 nm).

The notation Cu(thin) indicates that the thickness of the spacer layer is immaterial as long as it is smaller than the mean free path in copper. The precise choice of lead lengths is subject to uncertainty due to the approximations needed to model finite width and reservoir effects in a one-dimensional Boltzmann equation calculation of spin valve transport.\textsuperscript{52}

A. Computational Details

We solve the stochastic LLG equation using the Ito calculus\textsuperscript{69} and a numerical method described by Milstein.\textsuperscript{70} The simulations proceed by fixing the external field $H$ and sweeping the current density $J$ in steps of size $\delta J$. Before changing to the next value of $J$, we integrate the LLG equation for a “waiting time” $t^*$ using $N$ time steps of length $\delta t$. After each time step, we use the instantaneous value of the angle $\theta$ between $\mathbf{M}$ and $\mathbf{m}$ and the results of Ref. 71 to evaluate the instantaneous magnetoresistance $R(\theta)$. A time-average over these $N$ values gives the resistance we report for each $J$.

Fig. 4 shows the calculated high-field and low-field magnetoresistance as a function of $J$ for three values of the simulated sweep rate $SR = \delta J/t^*$. The curves in this figure are averages over 20 realizations of the stochastic simulation. In each realization, the system switches abruptly at a particular value of current between states with distinctly different magnetoresistance (to be discussed below). Since the switching current depends on the realization, an average over essentially vertical transitions at slightly different switching currents gives the not-quite-vertical lines seen in the figure. As expected,
the hysteresis loops close as the sweep rate decreases. Less obviously, the rate of closing is much greater at high field than at low field. It is important to appreciate that the slowest sweep rate we can practically use in our simulations [10^{11} A/(cm^2-s)] is still five orders of magnitude faster than the sweep rate used in the Cornell experiments.

For fixed values of $H$ and $J$, the $N$ values of resistance collected between $t = 0$ and $t = t^*$ constitute a time series for the resistance. Spin valves are Ohmic devices, so the Fourier transform of this series is proportional to the associated power spectrum. We use this numerical data below to compare with the microwave noise data reported in Ref. 11.

B. $J$-$H$ Phase Diagrams

Fig. 5 compares spin valve “phase diagrams” at $T = 3$ K, $T = 300$ K, and $T = 3000$ K for our minimal model. The diagrams were constructed by sweeping the current twice (once increasing the current and once decreasing the current) for each value of $H$. There is some noise at higher temperature because we did not average over multiple realizations of the simulation. Solid lines divide each diagram into phase fields with labels like A, B and A/B. The latter means that the field is occupied by phase A when the current is scanned from left-to-right in the diagram and by phase B when the current is scanned from right-to-left. Thus, a label like A/B is a signal that hysteresis is present.

The phase fields in Fig. 5 are labelled P (parallel), AP (anti-parallel), IPP (in-plane precession) and OPP (out-of-plane precession). The static P and AP states are labelled by the relative orientation of $\mathbf{m}$ and $\hat{z}$. The precessing states are identified from the microwave power (not shown) as described above. IPP denotes a dynamic state where $\mathbf{m}$ precesses symmetrically (or nearly so) around an axis that lies in the $y-z$ easy plane. OPP denotes a dynamic state where $\mathbf{m}$ precesses symmetrically (or nearly so) around an axis that does not lie in the easy plane. Sec. 11 describes these states in more detail.

We focus first on the 3 K diagram. This is similar (but not identical) to $T = 0$ K diagrams published by others using the symmetric Slonczewski spin-transfer torque. Using sharp peaks in the measured noise power spectrum to identify states of stable precession, Kiselev et al. pointed out the topological similarity between their computed $T = 0$ K phase diagram and their measured $T = 300$ K phase diagram.

When $H$ exceeds the coercive field, our 3 K phase diagram shows hysteresis for the P$\leftrightarrow$IPP and OPP$\leftrightarrow$AP phase transitions. The experiment shows no hysteresis in this regime (see below). At low field, the P $\rightarrow$ AP transition occurs abruptly while the reverse-current AP $\rightarrow$ P transition does not. Instead, there is a long, skinny, triangular-shaped P/IPP phase field within which the magnetization $\mathbf{m}$ exhibits stable, elliptical precession around the $-\hat{z}$ axis. The precession amplitude increases as the current becomes more negative. The system crosses the phase boundary into the P phase when the precession angle between $\mathbf{m}$ and $-\hat{z}$ exceeds 90° and the vector $\mathbf{m}$ spirals irreversibly toward $\hat{z}$. We will see below that this asymmetry has its origin in the details of the dependence of the spin-transfer torque on the angle between the free layer and the fixed layer.

We draw special attention to the lower limit of the OPP/AP phase field in the 3 K phase diagram. The perfectly horizontal portion of this phase boundary is an artifact of the current scanning mode used to generate the diagram. If we fix $J$ and scan the external field $H$ from large values to small values, the OPP phase does not give way to the AP phase until the dashed line in the diagram is crossed. The exact shape of this boundary depends on the $H$-scan rate, but it is reasonable to suppose that the corresponding horizontal phase boundary found in Ref. 11 may also be an artifact of the method of taking data.

Reading Fig. 5 from left to right shows that the regions of hysteresis shrink as the temperature increases. More details can be seen in the line scans of Fig. 6. The effect of increasing temperature is very similar to the effect of decreasing the current density sweep rate in Fig. 4. Indeed, since our simulated current sweep rate is always much faster than experiment, the temperatures indicated on the phase diagrams in Figure 5 must be regarded as nominal. The true phase diagram at each temperature we show should exhibit less hysteresis. Equivalently, each panel actually corresponds to a lower physical temperature than the temperature we quote. Thus, our $T = 3000$ K diagram indicates (qualitatively) how the 300 K phase diagram might look if we could use current sweep rates comparable to those used experimen-
FIG. 5: Minimal model dynamic phase diagrams for a Cu(80 nm)/Co(40 nm)/Cu(thin)/Co(3 nm)/Cu(10 nm) spin valve. Left panel: $T = 3$ K; middle panel: $T = 300$ K; Right panel: $T = 3000$ K. For fixed $H$, a bistable region labelled A/B exhibits the A state when $J$ is scanned from left to right and the B state when $J$ is scanned from right to left. The correspondence needed to compare with Ref. 11 is $10^8$ A/cm$^2$ ↔ 10 mA. The dashed curve is the OPP→AP phase boundary for a field scan from large $H$ to small $H$ at fixed $J$.

FIG. 6: Temperature dependence of the magnetoresistance obtained by averaging the results of 20 realizations of the stochastic simulation. Upper panel: $\mu_0 H = 0.05$ T; Lower panel: $\mu_0 H = 0.002$ T.

FIG. 7: Telegraph noise in a time-series of the magnetoresistance. The data was collected on the high-temperature boundary between the AP phase and the OPP phase ($\mu_0 H = 0.04$ T, $J = 0.7 \times 10^8$ A/cm$^2$).

Our highest temperature simulation shows P↔AP hysteresis when $H$ is small and complete reversibility when $H$ is large. This resolves the disagreement between theory and experiment noted above. Moreover, state-to-state switching characterizes every reversible phase boundary. Fig. 7 illustrates this for the dynamics of switching between the anti-parallel AP state and out-of-plane precession (OPP). The time-series data for the magnetoresistance was collected on the OPP/AP phase boundary at 3000 K. Clearly, the system switches back and forth between the AP state (small fluctuations around unit normalized resistance) and the OPP state (periodic oscillations of the normalized resistance between zero and one). Experiments show precisely this sort of telegraph noise if we replace the full scale excursions of the OPP resistance with small scale fluctuations around the average resistance of the OPP state. We are not aware of experiments that study the telegraph noise at our 300 K IPP/OPP boundary or our 3000 K P/OPP boundary. Indeed, at the latter, our simulations actually show random switching between three states: AP, IPP, and OPP.

The variations of the computed resistance near the 3000 K P/OPP and OPP/AP phase boundaries lead to two peaks in the differential resistance, $dV/dI = R + I dR/dI$. These agree well with the peaks in $dV/dI$ observed experimentally. On the other hand, Kiselev et al. identify a “W”-phase that is completely absent from our 3000 K phase diagram. However, the experimen-
tal W-phase field appears exactly where our model predicts OPP/AP phase bistability at 3 K and 300 K (two left panels of Fig. 5). The experimental W-phase is microwave quiet above the experimental low frequency cutoff (0.1 GHz) and it exhibits a magnetoresistance that is slightly, but distinctly, smaller than that of the AP configuration. This would occur in our macrospin model if the free layer were frozen into a static configuration with \( \mathbf{m} \) neither parallel nor anti-parallel to \( \mathbf{M} \). We will return to the W-phase when we discuss micromagnetic simulations in Section V.

Quantitatively, our calculated coercive field is about half the experimental value. This discrepancy may reflect an inaccurate description of the shape (and therefore the magnetostatic anisotropies) of the free layer. Another contributory effect is our complete neglect of dipolar coupling to the fixed layer. At low \( T \), we also find that the magnitude of the critical current \( J^+ \) for the P\( \rightarrow \)AP transition is much greater than the magnitude of the critical current \( J^- \) for the AP\( \rightarrow \)P transition. Experiments show that \( J^+ \) and \( J^- \) are more symmetric around zero current.

The reason for our calculated behavior is the difference between \( \eta(0) \) and \( \eta(180^\circ) \) for the Slonczewski torques in Fig. 3. Our simulations at 3000 K more nearly resemble the experiments at 300 K because \( J_T^+ \) decreases strongly with temperature while \( J_T^- \) is nearly temperature independent.

\section*{C. Precession Frequency}

The gray/color scale in Fig. 8 quantifies the relative microwave power (on a logarithmic scale) at frequency \( f \) as a function of magnetic field for two values of current density \( J \). The numerical data was obtained by Fourier transforming our simulated time series data for the magnetoresistance. The narrow bands of peak microwave power trace out the frequency \( \omega(H) \) of stable precession (and its harmonics). The left panel corresponds to small-amplitude, noise-driven, in-plane precession at a value of current just before the parallel phase becomes unstable to steady in-plane-precession. As with the experimental data\textsuperscript{11-12}, \( \omega(H) \) in this regime can be described by the Kittel equation (black curve) for thin film magnetic resonance.\textsuperscript{23} In the notation of Appendix I, the resonance frequency is

\begin{equation}
\omega_K = \gamma \sqrt{|H + (h_Y - h_Z)M_s| |H + (h_X - h_Z)M_s|}.
\end{equation}

Our simulation data agree with \( 2\omega_K \) because the periodicity of the resistance is twice the periodicity of the magnetization oscillation frequency. No analytic theory is available for comparison with our results at a higher value of \( J \) (right panel) where large amplitude out-of-plane precession occurs. But our results do show the same relative magnitude and \( H \)-dependence as seen in the experiments.

Fig. 9 shows the relative microwave power at frequency \( f \) as a function of increasing \( J \) (top panel) and decreasing \( J \) (bottom panel). Similar plots for comparison with experiment have been presented by others using the symmetric Slonczewski torques\textsuperscript{11-12} and the sine torque.\textsuperscript{20} The zero power regions at low and high \( J \) correspond to the static P and AP magnetization states. In between, the narrow bands of peak microwave power trace out \( \omega(J) \) (and its harmonics) for stable precession. Just above the limit of the parallel state, there is a very narrow range of in-plane precession where \( \omega(J) \) decreases monotonically. At slightly higher \( J \), the system evolves to a state of out-of-plane precession (OPP) where \( \omega(J) \) first increases and then decreases. Comparison of the two panels in Figure 9 illustrates the hysteresis present at this low temperature.

Our results for \( \omega(J) \) do not agree with observations for real spin valves.\textsuperscript{11-12} Putting aside the fact that no hysteresis is seen in the experiments (which we attribute to the current sweep rate as discussed above), the experimental data always show that \( \omega \) decreases as \( J \) increases. Naively, it is as if in-plane precession persisted all the way to the anti-parallel state with no intervening state of out-of-plane precession. This is a serious issue because in our model, in-plane precession occupies an extremely small
FIG. 9: Microwave power at different frequencies as a function of $J$ at $T = 3$ K and $\mu_0 H = 0.05$ T. The gray/color scale is logarithmic. Left panel: current scan from left to right. Right panel: current scan from right to left. The narrow bands of peak power represent the frequency $\omega(J)$ of stable precession. The black traces are the magnetoresistance in arbitrary units.

portion of the $J$-$H$ phase diagram.

D. Precession Trajectories

To help shed light on our simulation results for $\omega(J)$, it is instructive to analyze the relationship between this quantity and the trajectory of the tip of $\hat{m}$ on the unit sphere. We will call this the orbit of the precessional motion. Without loss of generality, we set $h_Y = h_Z = 0$ and retain only the external field $\mathbf{H} = H\hat{z}$ and the local, out-of-plane demagnetization field $\mathbf{H}_d = -h_X \hat{m}_x \hat{x}$. It is crucial that the magnitude $H_d$ changes along the trajectory because the component $\hat{m}_x$ of $\hat{m}$ changes along the trajectory.

It is common to think of precession as the steady motion of a vector on a cone that makes a small angle with respect to its symmetry axis. The orbit in this case is a circle. The precessional states in the present problem are more complicated. Fig. 10 shows two large amplitude, saddle-shaped, in-plane precession (IPP) orbits for two nearby values of $J$. We call these “in-plane” precession modes because each orbit moves symmetrically (or nearly so) around an axis (the $z$-axis) that lies in the easy $y$-$z$ plane.

Let us partition each orbit into two segments. The short thick segments lie near the easy plane where the demagnetization field $H_d$ is smaller than the external field $H$. Along these segments, the orbital azimuthal angle $\phi$ precesses mainly around $\mathbf{H}$ with angular speed $\gamma H$. Along the remaining segment of each orbit, $H_d$ is larger than $H$ and the orbital polar angle $\theta$ precesses mainly in the $x$-$y$ plane.

FIG. 10: In-plane precession (IPP) orbits for two nearby values of $J$. The thick segments are points on each orbit where the magnitude of the demagnetization field $\mathbf{H}_d = -h_X \hat{m}_x \hat{x}$ is smaller than the magnitude of the external field $\mathbf{H} = H\hat{z}$. The $y$-$z$ easy plane and the equatorial circle of the unit sphere in the $x$-$y$ plane are indicated as guides to the eye.

FIG. 11: Out-of-plane precession (OPP) orbits. The geometry is the same as Fig. 10 except that the north (N) and south (S) poles of the unit sphere are indicated. The orbit labelled “AS/SS” is produced by Slonczewski’s spin-transfer torque. Along the thick segment, the spin-transfer torque and demagnetization field torque point in opposite directions. The orbit labelled “sine” is produced by a sine-type spin-transfer torque for the same value of $J$.

FIG. 11: Out-of-plane precession (OPP) orbits. The geometry is the same as Fig. 10 except that the north (N) and south (S) poles of the unit sphere are indicated. The orbit labelled “AS/SS” is produced by Slonczewski’s spin-transfer torque. Along the thick segment, the spin-transfer torque and demagnetization field torque point in opposite directions. The orbit labelled “sine” is produced by a sine-type spin-transfer torque for the same value of $J$. 
around $\mathbf{H}_d$ with angular speed $\gamma H_d$. Fig. 10 shows that the angular range swept out by both the thick and thin segments increases as the current density (and the spin-transfer torque) increases, i.e., the total arc length of the orbit increases. Since the orbital speeds change very little with $J$, we conclude that the orbital period increases as current density increases. This implies that $\omega(J)$ is a decreasing function for in-plane-precession orbits.

As $J$ continues to increase, the apices of the two thick segments of the in-plane precession saddle orbit approach and then touch one another near the negative $z$-axis. When this occurs the orbit bifurcates into two elliptical orbits, each centered on an out-of-plane axis not far from the $x$-axis.3,11,29,30 Precessional states at higher current density correspond to one or the other of these out-of-plane (OPP) trajectories, e.g., the AS/SS orbit in Fig. 11. This orbit precesses mostly around $\mathbf{H}_d$. Spin-transfer torque tends to push the orbit away from the easy plane in the northern unit hemisphere. The effect on the orbit in the southern unit hemisphere is more complex. The net result is that the "center" of the orbit moves away from the easy plane. In other words, as the current density increases, the component $\hat{m}_x$ of $\hat{m}$ increases, which increases $H_d$, and thus increases the frequency $\gamma H_d$ of the orbit.

Along the thick segment of the out-of-plane orbit, the spin-transfer torque and the torque from the demagnetization field point in (nearly) opposite directions. This means that the net torque, and thus the orbital speed along that segment, decreases as $J$ increases. Eventually, this slowing down overwhelms the speeding up described just above and the total orbital period begins to increase. This is why $\omega(J)$ decreases for the largest values of $J$ where precession occurs in the top panel of Fig. 9.

### IV. BEYOND THE MINIMAL MODEL

There are two major discrepancies between the Cornell experiment and our minimal model results: the variation of the precession frequency $\omega$ with current density $J$ and the absence of a microwave quiet "W-phase". Within the context of the macrospin model, we examined several variations of our model, mostly with the hope they would improve the agreement between theory and experiment. We studied the influence of (A) a sine-type spin transfer torque for the standard geometry; (B) asymmetric vs. symmetric Slonczewski spin-transfer torque for a special asymmetric geometry; (C) the current-induced effective field that arises due to incomplete absorption of transverse spin currents; (D) spin-pumping; and (E) angle-dependent Gilbert damping.

#### A. Sine Spin-Transfer Torque

Fig. 3 shows the geometry-independent "sine" torque that is widely used in the literature. The top left panel in Fig. 12 shows the 3 K phase diagram when this sine torque replaces the AS/SS torque. Several differences with the corresponding Slonczewski torque phase diagram (left panel of Fig. 5) should be noted.

First, with a sine torque, the low-field P→AP transition is mediated by in-plane precession in the same way that precession mediates the AP→P transition for both the sine and Slonczewski torques. This occurs because $\sin \theta$ is symmetric around $\theta = \pi/2$ while the minimal model torque is not. Second, the sine torque generates no hysteresis in the high-field transitions P↔IPP and IPP↔OPP. Third, the lower limit of the OPP phase boundary determined by a field scan from large $H$ to small $H$ (dashed curve) greatly reduces the size of the AP phase field compared to the Slonczewski case. This feature does not appear to have been noticed in previous discussions of this phase diagram.28,29

Unlike the Slonczewski torque, increasing current or field eventually drives the sine torque model to a transition from out-of-plane precession (OPP) to a static phase where the macrospin $\mathbf{m}$ is "fixed" (F) at some angle between zero and $\pi$. This is intriguing because the magnetoresistance and microwave power characteristics of this phase match exactly to those of the experimentally observed "W-phase". Unfortunately, the location of the F phase in the sine torque phase diagram does not agree with the location of the W-phase in the experimental phase diagram (see the penultimate paragraph of Sec. 3).

The bottom left panel in Fig. 12 shows the 3000 K phase diagram for the sine torque macrospin model. Compared to the corresponding diagram for the minimal model (right panel of Fig. 5), thermal effects eliminate OPP/AP bistability only when $J$ is small. Hysteresis between these phases remains when $J$ is large. In this sense, the sine torque model is more resistant to thermal fluctuations than the Slonczewski torque model.

Finally, the out-of-plane precession frequency for the sine torque is a strictly increasing function of $J$. The argument is similar to the one in Sec. 3 for the Slonczewski torque. However, as the current increases, the different angular dependence of the sine torque causes the orbit of $\hat{m}$ to push steadily away from the easy plane everywhere and contract on the unit sphere (see Fig. 11). The frequency $\gamma H_d$ increases monotonically because the demagnetization field $H_d$ increases. The outward motion and areal contraction of the orbit continues as the current increases until the orbit area shrinks to a single point on the unit sphere. This is the signature of the fixed (F) phase.

#### B. AS vs. SS Spin-Transfer Torque

The AS/SS curve in Fig. 4 shows that the asymmetric Slonczewski torque used in our minimal model is essentially identical to the symmetric Slonczewski torque for the spin valve geometry of Ref. 11. This is not always the
case. For example, compared to the geometry of Kiselev et al., a spin valve with film thicknesses, Cu(10 nm)/Co(40 nm)/Cu(thin)/Co(3 nm)/Cu(180 nm), is very asymmetric. The Cu/Co bilayers on opposite sides of the spacer layer are very different: the left bilayer is mostly ferromagnet, the right bilayer is mostly non-magnet. The difference between the symmetric and asymmetric Slonczewski torques for this geometry is still small (compare the two dashed curves in Fig. 3). Nevertheless, it is large enough to produce small-angle, in-plane precession that “rounds” the low-to-high resistance jump in the AS hysteresis curve at the P→AP transition in the lower panel of Fig. 13. The same panel shows similar precessional rounding for the sine-type spin-transfer torque. However, the latter rounding disappears when shape anisotropy is turned off.

Fig. 13 also shows that the critical current \( J_c^+ \) for the P→AP transition differs for all three spin-transfer torques while the critical current \( J_c^- \) for the reverse AP→P transition distinguishes only the sine torque. This is a consequence of the fact that \( J_c^+ (J_c^-) \) is inversely proportional the slope of the torque function \( \eta(\theta)\sin \theta \) (plotted in Fig. 3 at \( \theta = 0 \) (\( \theta = \pi \)). The fact that \( J_c^- \) is smaller for the AS torque than for the SS torque suggests that an asymmetric geometry like the one above may be desirable for some applications.
C. Current-Induced Effective Fields

We mentioned in Sec. II E that a current-induced torque that acts like an effective external magnetic field can arise due to incomplete absorption of a transversely polarized spin current at the interface between the spacer and the free layer. A recent experimental report has been interpreted by its authors to mean that the size of this torque—displayed in Eq. (10)—is much larger than theoretical estimates. Accordingly, Fig. 12 shows how the spin torque 3 K phase diagram changes if we augment the sines torque (top middle panel) and the minimal model torque (top right panel) by an effective field torque that is 20% of the spin-transfer torque, as suggested by this experiment. For comparison, the bottom middle and bottom right panels respectively show the phase diagrams for these two situations at 3000 K. We find that the topology of the phase diagram does not change, although the precise positions of the phase boundaries do. The qualitative behavior of the precession frequencies is not affected.

D. Spin-Pumping

The original discussion of spin-pumping focused on the enhancement of Gilbert damping that occurs when a normal metal is in intimate contact with a precessing thin film ferromagnet. Subsequent work has emphasized that the torque due to spin-pumping is generally of the same order of magnitude as spin-transfer torques. Since the analytic form of the torque $N_{sp}$ in Eq. (11) differs considerably from simple damping for, e.g., large-angle, out-of-plane precessional motion, this raises the possibility that spin-pumping alters the dynamical behavior of a spin valve more profoundly than merely enhancing the Gilbert damping.

In the small angle limit, the parameters for intrinsic Gilbert damping and spin-pumping suggested in Ref. 48 for the Co/Cu/Co system (Table I) produce a total effective Gilbert damping of $\alpha_{eff} = 0.148$. Therefore, in Fig. 14 we compare the phase diagram at 3 K obtained with our minimal model (no spin pumping) using $\alpha = \alpha_{eff}$ (solid lines) with the phase diagram obtained including both (reduced) Gilbert damping and the spin-pumping torque density $N_{sp}$ (dashed lines). The small differences we find between the two show that spin-pumping does not much affect the sort of precessional motion produced by our minimal model. There is also no qualitative change in the current dependence of the precession frequency. We conclude that neither effective fields nor spin pumping affects the agreement between experiment and the minimal model.

E. Angle-Dependent Gilbert Damping

The numerical value of the Gilbert damping constant $\alpha$ in Eq. (2) is usually extracted from ferromagnetic resonance or Brillouin light scattering experiments. Since the magnetization is never tilted far from equilibrium in these situations, it is relevant that Back et al. reported an effective increase in the damping constant for large magnetization rotation angles in cobalt films under pulsed field conditions. More recent pulsed-field experiments have been successfully analyzed using conventional Gilbert damping. Since transient magnetization dynamics is a common feature of all these experiments, it is not obvious that the results address the validity of the constant $\alpha$ approximation for large-angle, steady precession of the sort discussed in this paper. With one exception we are unaware of any models that allow the damping constant to vary during the course of precession.

A glance back at Fig. 9 shows that the precession frequency $\omega(J)$ decreases monotonically (as seen in experiment) for in-plane-precession and also for out-of-plane precession near the boundary with the anti-parallel state. Using the damping “constant” ansatz

$$\alpha(\theta) = a + b \sin^2 \theta,$$

we have been able to produce dynamical phase diagrams with (i) only in-plane-precession or (ii) only out-of-plane precession with (in both cases) the “correct” behavior for $\omega(J)$, or nearly so. Unfortunately, other features appear in the simulated phase diagram that do not appear in the data, e.g., an extended region of precession when the external field $H$ is less than the coercive field. It may be possible to fine-tune the phase diagram to the desired form, but this seems unwarranted without some justification for Eq. (15) and the relative paucity of theoretical information about damping far from equilibrium.

V. MICROMAGNETICS

Our macrospin approach to the Landau-Lifshitz-Gilbert (LLG) equation replaces the free layer magne-
We have studied the Landau-Lifshitz-Gilbert (LLG) dynamics of a single macrospin as a model for current-driven magnetization motion in the free layer of a spin valve. We parameterized our model specifically to compare our results with those reported by Kiselev et al. for a Cu/Co/Cu nanopillar. Due to the simplicity of the model (compared to micromagnetics), we were able to explore systematically the effects of temperature, spin-pumping, current-induced effective fields, various forms of spin-transfer torque, and angle-dependent damping. We focused most of our attention on a “minimal model” where Slonczewski’s spin-transfer torque supplements the terms usually found in the LLG equation.

**Low-Field Behavior:** Our minimal macrospin model captures the essential features of the experiment when the external field $H$ does not exceed the coercive field of the free layer. As a function of current density $J$, there is hysteretic switching between parallel and anti-parallel orientations of the free layer and the fixed layer. In the experiment, the critical currents for P$\rightarrow$AP and AP$\rightarrow$P switching have opposite sign but are approximately equal in magnitude. This is not a feature of our $T = 3$ K phase diagram, but it is much more nearly true in our simulation at 3000 K, where thermal fluctuations are large enough to mimic the effect of the (slow) current sweep rate used in the experiment. The scale we calculate for $H$ is about half as large as seen in the experiment.

**High-Field Behavior:** The macrospin model correctly models noise-driven, low amplitude, in-plane precession when $H$ is larger than the coercive field and the current density is low. The existence of large-amplitude, in-plane and out-of-plane precession at higher $J$ agrees qualitatively with observation, but the precession frequency function $\omega(J)$ is not monotonically decreasing as found in experiment. The simulation predicts peaks in $dV/dI$ associated with telegraph-noise switching between two (or more) states of magnetization. These peaks are present in the experiment, as is two-state telegraph noise. We find an OPP/AP bistable phase field that is occupied in the experiment by a microwave quiet “W” phase. Micromagnetic simulations by others suggest that that vortex creation and annihilation occurs in this phase field.

**Other Effects:** The phase diagram of the sine-torque model differs mostly in detail with the phase diagram of the minimal model. An exception is the presence of a high-field, high current “fixed” phase for the sine torque where the macrospin freezes into a fixed angle with re-
spect to the fixed layer. This phase does not seem to occur in micromagnetic simulations. Another exception is the relative persistence of the OPP phase when we scan from high values of $H$ to low values of $H$. This behavior is also absent from the micromagnetics simulations. Spin-pumping and current-induced magnetic fields do not change the phase diagram in any significant way. Large topological changes do occur if we allow the Gilbert damping parameter to change with angle, but we have no guidance for the form $\alpha(\theta)$ should take. This seems like a fruitful direction for future research.

VII. ACKNOWLEDGMENT

The authors acknowledge useful discussions about spin valve experiments with Ilya Krivorotov, Bob Buhrman, Jack Sankey, Bill Rippard, Steve Russek, Tom Silva, Matt Pufall, Sergei Urazhdin, Jack Bass, and Mark Covington. One of us (J.X.) is grateful for support from the Department of Energy under grant DE-FG02-04ER46170.

APPENDIX: ENERGY EXPRESSION

The energy of the free layer includes a Zeeman energy $E_Z$ from the external field $H$, a magnetostatic shape anisotropy energy $E_s$, and a surface anisotropy energy (parameterized by $K_u$) that vanishes in the limit that the free layer thickness $d \to \infty$.

The Zeeman energy is

$$E_Z = V \mu_0 M_s \hat{m} \cdot H.$$  \hspace{1cm} (16)

The shape anisotropy energy is

$$E_s = V \frac{1}{2} \mu_0 M_s \hat{m} \cdot \mathbf{H}_d = V \frac{1}{2} \mu_0 M_s^2 \hat{m} \cdot \mathbf{N} \cdot \hat{m},$$  \hspace{1cm} (17)

where $\mathbf{H}_d = M_s N \cdot \hat{m}$ and $\mathbf{N}$ are the demagnetization field and demagnetization tensor, respectively. Referring to Fig. 2 the total energy is

$$E = \frac{1}{2} \mu_0 M_s^2 V [L \cos^2 \theta + M \sin^2 \theta \sin^2 \phi + N \sin^2 \theta \cos^2 \phi] - \mu_0 M_d VH \cos \theta - \frac{2VK_u}{d} \sin^2 \theta \cos^2 \phi \hspace{1cm} (18)$$

where $L, M, N$ are the demagnetization factors for the $\hat{z}, \hat{y}, \hat{x}$ directions. These terms can be combined to give

$$\frac{2E}{\mu_0 M_s^2 V} = h_L \cos^2 \theta + h_M \sin^2 \theta \sin^2 \phi + h_N \sin^2 \theta \cos^2 \phi - 2h \cos \theta,$$  \hspace{1cm} (19)

where $h = H/M_s$, and

$$h_L = L - \frac{H_k}{M_u}, \hspace{0.5cm} h_M = M, \hspace{0.5cm} h_N = N - \frac{4K_u}{\mu_0 M_s^2 d}.$$  \hspace{1cm} (20)

If we model the thin free layer as a very flat ellipsoid with semi-axis $a \geq b \gg c$, Eqs. (2.23-25) in Ref. 80 give

$$L = \frac{c}{a} (1 - e^2)^{1/2} \frac{K - E}{e^2},$$

$$M = \frac{c}{a} \frac{E - (1 - e^2)K}{e^2 (1 - e^2)^{1/2}},$$

$$N = 1 - \frac{cE}{a (1 - e^2)^{1/2}},$$

where $K$ and $E$ are complete elliptic integrals with argument $e = \sqrt{1 - b^2/a^2}$. For the nominal geometry of Ref. 80 we have $2a = 130 \text{ nm}, 2b = 70 \text{ nm}, 2c = 3 \text{ nm}$, so $L \approx 0.017$, $M \approx 0.035$, $N \approx 0.948$.
