(Dated: May 12, 2015)

We present a simple game model where agents with different memory lengths compete for finite resources. The equilibrium analysis of these competitions began with von Neumann [1] and Nash [2]. The theory of games has since found applications in genetics, ecology, economics and sociology [3–6]. Computational implementation of games leads to agent-based models, which may be of particular importance in understanding the behaviour of financial systems [7]. For example, the particularly successful minority game model [8] captures the competition between intelligent agents with a restricted form of memory. Recent work suggest such games may be generalised leading to clearly separated regimes of behaviour [9, 10]. In general, understanding the complex collective behaviour arising from the non-linear interactions between individuals is a major challenge for statistical physics [11, 12].

In this Letter we present a simple game model: in each round, each agent will switch urns using the probabilities between urns, which are deterministic functions of $\Delta t$. Agent dynamics is encoded in transition probabilities between states, which may be random variables uniformly distributed on $[0, 1]$ and fixed. Let $\Delta t$ be the fraction of agents in urn 1, then the difference in the average payoffs between urn 1 and urn 2 is

$$\Delta \tau := \frac{1}{\tau} \sum_{s=0}^{\tau-1} \left[ \frac{U_2(t-s)}{n(1-\phi_{t-s})} - \frac{U_1(t-s)}{n\phi_{t-s}} \right].$$

We refer to $\tau$ as the “memory length” of the agents. Agent dynamics is encoded in transition probabilities between urns, which are deterministic functions of $\Delta \tau$. At each round, each agent will switch urns using the proba-
We define another by interpreting the payoff as reproduction rate. The number of moves at each step is $\phi$. In Figure 2 we have $\epsilon = 10$. For larger $\epsilon$, stable. For larger $\epsilon$, $\epsilon = 10^{-3}$, $\epsilon = 10^{-3}$. Memory values are $\tau \in \{5, 50, 500\}$ (triangles, squares, circles). Dashed line is solution to equation (15) when $\tau = 500$ and $\omega, \beta, \epsilon$ are as above.

Simulations (instability) – We simulate the model for a series of values of $\tau$ when $n = 10^6$. Two different values of $\epsilon$ are used; in Figure 1 we have $\epsilon = 10^{-3} \gg \tau$ and in Figure 2 we have $\epsilon = 10^{-5}$. For $\epsilon = 10^{-6}$, the expected number of moves at each step is $< 1$, and $\phi$ appears very stable. For larger $\epsilon$, $\phi$ experiences much larger fluctuations about the steady state value, driven by the yield process. For shorter memory values these fluctuations are random, but as $\tau$ approaches $\epsilon^{-1}$, periodic oscillations appear and dominate. The appearance of these stable oscillations at critical memory, $\tau_c$, is known as a Hopf bifurcation [20]. By allowing agents access only to the mean of their memory, we implicitly assume that changes in the expected payoff over the course of their memory, brought about by oscillations, are too subtle for them to infer from noise.

Simulations (coexistence) – We now investigate how agents with two different memories compete against one another by interpreting the payoff as reproduction rate. We define $\delta$ and $\gamma$ as the rates of death, and reproduction per unit payoff, respectively. Reproduction is assumed to occur before death in each round, but in practice the probability of any one agent reproducing and dying in the same round is extremely small for the $\gamma, \delta$ values we choose. Letting $p_i(t)$ be the number of agents with memory $\tau$ in urn $i$ at time $t$ we set the probability of birth for an agent in urn $i$ to be

$$P(\text{birth}) = \frac{\gamma U_i(t)}{\sum_{\tau} p_i(t)}.$$  

(4)

The death probability for each agent is set equal to $\delta$. If populations are fixed in size and the system is not in an oscillatory state, then we expect that in equilibrium the longer memory agents will dominate the high yielding urn. Their long memory allows them to perceive smaller statistical advantages that are obscured by noise for the short memory agents. Using the thermodynamic analogy, the higher temperature (shorter memory) agents are more likely to make moves which leave them in an urn with a lower expected payoff, corresponding to a higher “energy” state. Above zero temperature, and in the absence of oscillations, the high yield urn will be under-exploited, placing high memory agents at an advantage. This effect can be observed in Figure 3 where we have simulated a mixed population of two memories $\tau \in \{10, 1000\}$ beginning with a ratio of 10:1 short memory to long memory agents. We see that initially the advantage afforded the long memory agents causes their population to grow, whereas the short memory agents reduce in number. Were this advantage to be sustained indefinitely then we would expect the short memory agents to eventually disappear, but in fact the populations stabilize. This effect appears because the long memory agents cause oscillations to develop once they are in sufficiently high concentration. In the presence of oscillations the short memory agents have an advantage because they can quickly observe opportunities offered by the oscillating
payoffs. We therefore expect the system to evolve to the point where oscillations are just beginning to form. We may observe this evolution by making use of the variance of \( \phi_t \) as an order parameter which captures proximity to the Hopf bifurcation point. In Figure 3 we see that at a critical ratio of short to long memory agents, the variance climbs rapidly, stabilizing just below the value seen in a system where all agents have memory \( \tau_c \), but all other parameters are equal. In this way the Hopf bifurcation may be viewed as a self organized state.

**Analysis (equilibrium)** – We consider the behaviour of the model as \( \epsilon \to 0 \), allowing us to view it as an urn model in the Ehrenfest class where agents independently make transitions using state (\( \phi_t \)) dependent probabilities. Provided \( \tau < \epsilon^{-1} \), the fraction \( \phi_t \) may be approximated by a constant \( \phi \) during the window over which payoff averaging takes place. In this case, by the central limit theorem, the marginal distributions of \( \Delta_t \) for each \( t \) are approximately normal \( N(\Delta, \sigma^2/\tau) \) where, from

\[
\Delta(\phi, \omega) := 1 - \frac{1}{\phi} - \frac{\omega}{\omega - \phi} \quad (5)
\]

\[
\sigma^2(\phi, \omega) = \frac{1}{\tau} \left( \frac{\omega^2}{\phi^2} + \frac{1}{(1-\phi)^2} \right) \quad (6)
\]

We now introduce a intermediate time scale \( T \) satisfying \( \tau < T < \epsilon^{-1} \) and define the time average \( \langle \cdot \rangle \), over a window of length \( T \)

\[
\langle W_{i \to j}(\Delta) \rangle(t) := \frac{1}{T} \sum_{s=t-T+1}^{t} W_{i \to j}(\Delta_s). \quad (7)
\]

This average is a random variable which, for constant \( \phi \), has expected value \( \mathbb{E}[W_{i \to j}(\Delta)] \) where the expectation is taken over the marginal distribution of \( \Delta \). The condition \( \tau < T < \epsilon^{-1} \) ensures that \( \phi \) is approximately constant over the window and that the variance of \( (W_{i \to j}(\Delta)) \) is proportional to \( T^{-1} \) (because \( \Delta_t \) and \( \Delta_{t+1} \) are dependent only when \( |t_2 - t_1| < \tau < T \)). As \( \epsilon \to 0 \), then assuming \( T \) is sufficiently large, the probability that an agent will make a transition \( i \to j \) during interval \( T \) approaches \( T \mathbb{E}[W_{i \to j}(\Delta)] \), equivalent to a memoryless (Ehrenfest class) model where transition probabilities are replaced with their expectations \( \mathbb{E}[W_{i \to j}(\Delta)] \). Averaging over the normally distributed difference \( \Delta \) we find that

\[
\langle W_{i \to j}(\Delta) \rangle \approx \mathbb{E}[W_{i \to j}(\Delta)] \approx \frac{\epsilon}{2} \left[ 1 + \tanh(\alpha \Delta) \right] \quad (8)
\]

To obtain this result, we have made the approximation \( \tanh(\beta \Delta) \approx \text{erf}(\sqrt{2} \beta \Delta / 2) \), allowing us to make use of the exact relationship \( \mathbb{E}[\text{erf}(\sqrt{2} \beta \Delta / 2)] = \text{erf}(\sqrt{2} \beta \Delta / 2) \). The constant \( \alpha \) acts as an effective inverse temperature and we see that increasing \( \tau \) “cools” the system closer to the inverse temperature \( \beta \), and in the limit \( \beta \to \infty, \alpha \propto \sqrt{\tau} \). To complete our analogy to a thermal urn model we now write the probability of finding the agents in a particular arrangement, or microstate, such that a fraction \( \phi \) are in urn 1, as \( p(\phi) \propto e^{-\alpha \mathbb{E}} \) where \( \mathbb{E} \) is an “energy” function. Considering two microstates separated by a single transition, and defining \( \delta \phi = 1/n \), then detailed balance requires that in equilibrium \( 2\alpha \Delta = \partial_\phi (\alpha \mathbb{E}) \delta \phi \). This condition allows \( \mathbb{E}(\phi) \) to be computed, in principle, by integration. A closed form approximation \( \mathbb{E}(\phi) \approx -n \ln (\phi^2 (1 - \phi)) \) is obtained by noting that \( \alpha \) depends weakly on \( \phi \) compared to \( \mathbb{E} \) so that \( \partial_\phi (\alpha \mathbb{E}) \approx \alpha \partial_\phi \mathbb{E} \). Summing over all microstates corresponding to macrostate \( \phi \) we have a Boltzmann probability distribution for \( \phi \)

\[
\mathbb{P} (\phi) = \frac{n!}{(n\phi)!(n(1-\phi))!} e^{-\alpha \mathbb{E}(\phi)} \tilde{Z}, \quad (10)
\]

where \( \tilde{Z} \) is the partition function. Taking the thermodynamic limit \( n \to \infty \), and making use of Stirling’s approximation, we find that the most likely (maximum entropy) fraction, \( \tilde{\phi} \), satisfies:

\[
\frac{1}{2n} \frac{\partial}{\partial \phi} \ln \mathbb{P} (\phi) = \alpha \tilde{\Delta} - 2\tilde{\phi} + 1 = 0. \quad (11)
\]

As the memory increases and the system cools we expect the agents to arrange themselves so that yields are shared more fairly. We therefore linearize (11) about the perfectly fair state, \( \phi = \omega / (1 + \omega) \), where agents in both urns receive the same expected payoff, finding that

\[
\tilde{\phi} \approx \frac{f(\tau) + \beta(1+\omega)^2}{2f(\tau) + \beta(1+\omega)^2}, \quad (12)
\]
where $f(\tau) = \sqrt{1 + \pi\beta^2(1 + \omega)^2}/(12\tau)$. The accuracy of this approximation is verified in Figure 1. For larger values of $\epsilon$ (Figure 2) agents move more quickly so the averaging effect damps fluctuations in transition rates less strongly, creating larger fluctuations in $\phi_t$. For finite $\beta$ the system cannot reach perfect fairness for any memory length, but in the limit $\beta \to \infty$ where the transition probabilities become step functions, we have that:

$$\hat{\phi} \approx \frac{\omega}{\omega + 1} \left[1 - \sqrt{\frac{\pi(\omega - 1)}{3\tau(\omega + 1)^2}} + O(\tau^{-1})\right].$$

From this we see that the distance away from the fair state decreases as $\tau^{-1/2}$ as the memory of the agents becomes large. However, we now show why increasing $\tau$ too far, when $\epsilon$ is finite, destabilizes the system.

**Analysis (instability)** – As $\tau$ increases, fluctuations in $\Delta_t$ due to the yield process are reduced but for finite $\epsilon$ we can no longer treat $\phi_t$ as a constant over the averaging window. It is instructive, therefore, to study the effect of variations in $\phi_t$, neglecting the variations in yield. Promoting $t$ to a continuous variable and replacing the urn yields with their mean values we have

$$\Delta_t \approx \frac{1}{2\tau} \int_{t-\tau}^{t} \left[\frac{1}{1 - \phi_s} - \frac{\omega}{\phi_s}\right] ds. \tag{14}$$

We then approximate the evolution of $\phi_t$ using the following delay differential equation:

$$\dot{\phi}_t = (1 - \phi_t)W_{2-\tau}(\Delta_t) - \phi_tW_{1-\tau}(\Delta_t). \tag{15}$$

A numerical solution to this equation is shown in Figure 2 along with simulation results using the same parameter values. The oscillations in the simulation are accurately captured by (15), but the stochastic yield disrupts their perfect periodicity. To discover the parameter values at which stable oscillations develop we linearize equation (15) by writing $\phi_t = \bar{\phi} + \psi_t$ where $\psi_t$ are small fluctuations and $\bar{\phi}$ is the constant fixed point, not necessarily stable, of equation (15). In terms of these new variables

$$\Delta_t \approx \bar{\Delta}(\bar{\phi}, \omega) + \frac{\sigma^2(\bar{\phi}, \sqrt{\omega})}{\tau} \int_{t-\tau}^{t} \psi_s ds \tag{16}$$

where the functions $\bar{\Delta}$ and $\sigma^2$ are defined in (16) and (19). After expanding the tanh functions in the transition rates to first order about $\bar{\Delta}(\bar{\phi}, \omega)$, we obtain the following linear delay equation

$$\dot{\psi}_t = -\epsilon \left[\psi_t + \frac{A}{\tau} \int_{t-\tau}^{t} \psi_s ds\right] \tag{17}$$

where $A = 3\beta\text{sech}^2[\beta\bar{\Delta}(\bar{\phi}, \omega)]\sigma^2(\bar{\phi}, \sqrt{\omega})$. To determine the stability of this equation we introduce an exponential trial solution $\psi_t = e^{\lambda t}$ where $\lambda = x + iy$. Substitution into equation (17) yields a characteristic equation with real and imaginary parts given by

$$x^2 - y^2 + \frac{eA}{\tau}(1 - e^{-\tau x} \cos \tau y) = 0 \tag{18}$$

$$2xy + eA \frac{e^{-\tau x}}{\tau} \sin \tau y = 0. \tag{19}$$

For sufficiently small memory, $\tau$, the real part, $x$, of the solutions to (18) and (19) is negative so the fixed point $\bar{\phi}$ is stable. As we increase $\tau$, $\lambda$ crosses through the imaginary axis, creating a switch to instability with oscillations of exponentially increasing magnitude. Although the full equation (15) shares this transition to instability, we find that the resulting oscillations are bounded. The appearance of these stable oscillations as $\tau$ passes through a critical value, which we denote $\tau_c$, constitutes the Hopf Bifurcation [20]. To compute $\tau_c$ we set $x = 0$ in equation (19) so that $\text{sinc}(\tau y) = A^{-1}$. Expanding the sinc function to second order about its root at $\pi/\tau$ and solving the resulting quadratic we find that

$$y \approx \frac{\pi}{2\tau} \left(3 - \sqrt{1 - 4A^{-1}}\right) \approx \frac{\kappa}{\tau} \tag{20}$$

which defines a new constant $\kappa$. Substitution of this solution into (15), yields the following expression for the critical memory length

$$\tau_c = \frac{\kappa^2}{\epsilon A(1 - \cos \kappa)}. \tag{21}$$

For example, for the parameter values used in Figure 2 we have $\tau_c \approx 400$, whereas the relevant critical value for Figure 1 is $\tau_c \approx 1.8 \times 10^9$. These values are in excellent agreement with simulations.

**Conclusion** – We have introduced a simple thermal urn model of competition between agents with memory. Increasing memory allows agents to more accurately determine the most productive strategy, and reduces the temperature of the model. However, if a sufficiently high concentration of long memory agents is present a limit cycle appears which reduces the competitiveness of long memory agents, leading to self organized Hopf bifurcation in a mixed memory model. The simplicity of our model, its connection to classical urn models, together with the fact that limit cycles arise naturally suggest it might be fruitfully generalized, and employed to study a variety of different games. For example our approach may be applied to the Rock Scissors Paper game [3], where agents, interacting pairwise, recall their last $\tau$ interactions. Although a larger memory provides better statistical data on the optimal strategy, at critical memory a limit cycle emerges about Nash equilibrium, destroying this competitive advantage [27]. Other natural extensions include the introduction of multiple urns to represent, for example, different financial stocks. In this case we would expect more complex patterns of oscillation [29]. Experimental research into the nature of human and animal memory [28–31] places emphasis on the “forgetting function” which describes how memories decay with time. Such a function, or greater powers of statistical inference, could be naturally incorporated into our analysis, and its effects on stability explored.
