ABSTRACT. First Cepheids observations using echelle-spectrograph HRS fed by Southern African Large Telescope (SALT) were realized during 2016. All spectra have been obtained in the medium resolution mode ($R \approx 31000-41000$) with high $S/N$ ratio near 50–220. All data were processed using package developed by authors based on the standard system of astronomical data reduction MIDAS. Using new echelle data we found the atmosphere parameters and chemical composition for 30 faint Cepheids of southern hemisphere, where for the most of these stars these results we obtained for the first time. 28 stars are Cepheids after the first-dredge up stage, while ASAS 075842-25336.1 and ASAS 1131714-6605.0 having remarkable Li $\lambda$ 6707.8 Å absorption line and anomalous CNO and Na content could be consider as first crossing of the Cepheids instability strip.

Keywords: Stars: Cepheids: atmosphere parameters; Cepheids: chemical composition

1. Introduction

The abundance gradient for the Galaxy as observational characteristic of the galactic disk is the most input parameter in any theory of galactic chemical evolution. Many questions concerning the present-day abundance distribution in the galactic disk, its spatial properties and evolution with time remain to be answered. To answer these questions it would be reasonably to use the Cepheids as the quite suitable probes of metallicity in the Galactic disc.

According to results of investigations for iron, for example, its abundance gradient displays a multimodal structure: a rather flat part in vicinity of the Sun, a small gradient in the outer part of the disk (here the distribution shows some scatter and all the stars are metal-deficient comparing to the stars from the solar vicinity), and a quite large negative gradient in the inner part of the disk in the range from 4 to 7 kpc, but it with a very small number of investigated stars, and poorer statistics.

Even though elemental abundance increases towards the galactic center, there are arise two questions: 1) what is the real behavior of the abundance distributions within the inner parts (less than 7 kpc) and more than 10 kpc? 2) what is the real one for the galactocentric distances more than 10 kpc?

Therefore, the main objective of our program is to observe additional Cepheids situated closer to the galactic center and situated too much far away from it in order to:
1) Constrain the metallicity distribution and its gradient in these regions;
2) Find the properties of the abundance distribution at galactocentric distances of less than 7 kpc and more than 10 kpc.
3) To extract the possible objects belonging to the Population II.

To realize this program we have used Southern African Large Telescope (SALT). Our observational
HRS and both instruments have very close type of Spectrograph (FEROS). FEROS looks very similar to echelle data from Fiber-fed Extended Range Optical package and it was developed for the reduction of echelle data. FEROS package which consist of huge amount of basic procedures for echelle data reduction.

The surface gravity log\( \log g \) was determined from the ionization equilibrium condition for Fe\(^{I} \) atoms. The microturbulent velocity \( V_t \) was determined from the condition for the Fe\(^{I} \) abundance derived from a set of lines being independent of their equivalent widths.

The effective temperatures \( T_{eff} \) were determined by a method based on the depth ratios of selected pairs of spectral lines most sensitive to the temperature. Several spectroscopic criteria (Kovtyukh, 2007) were used in this case. This method provide an internal accuracy of 10 – 30 K for \( T_{eff} \) (the error of the mean). The surface gravity \( \log g \) was determined from the ionization equilibrium condition for Fe\(^{I} \) and Fe\(^{II} \) atoms.

When estimating the atmospheric parameters and chemical abundances, we used the VALD oscillator strengths (Kupka et al., 1999) and model atmospheres from Castelli & Kurucz (2004).

3. RS Nor as a testing object

We used RS Nor as a testing object since its atmosphere parameters and chemical composition were determined earlier by Luck (2014). Our carbon and oxygen abundances estimations are close to ones from Luck (2014) paper, theresa sodium and iron show

78 objects with magnitude 10\(^{m} \leq V \leq 12\(^{m} \) have been selected from GCVS, ASAS and 2MASS catalogues. At now we have the results for spectra of 30 Cepheids. All these data are given in Table 1.
some less values ([Na/H] = +0.77 and [Fe/H] = +0.23 from Luck paper). All our data are given in Table 1.

4. Conclusions

Our analysis of the available spectra results to the following conclusions:

1. As seen from Table 1 all objects have metallicity values within the ranges of −0.3 − +0.4 dex that is an evidence of their belonging to Population I.

2. Our [Fe/H] estimates for these Cepheids are in good agreement with Luck & Lambert (2011) data for iron abundance gradient of Galaxy.

3. CNO- elements abundances in the whole show the typical values for yellow supergiants after first dredge-up stage. Carbon is in deficient, excepting ASAS 174603-3528.1, ASAS 182714-1507.1 and VW Cen. These Cepheids have metallicity over-abundance and their [C/Fe] relation give the deficient too. Nitrogen demonstrates overabundance except for case of ASAS 075842-2536.1. There are significant discrepancies of oxygen from the solar value.

4. Sodium is in overabundance, except ASAS 075842-2536.1. Magnesium abundance shows discrepancies and aluminium content is overabundant in most cases except for ASAS 073200-2529.3 and ASAS 065851-1344.2

5. Objects ASAS 075842-2536.1 and ASAS 131714-6605.0 have remarkable absorption line of lithium 6707.8 Å (see Figure 2), and anomalous CNO and Na content. Quite probably these stars are Cepheids, first time crossing the Cepheids instability strip (CIS).
