\textbf{ABSTRACT}

Adipose tissue (AT) is involved in dysmetabolism pathogenesis. Regional fat distribution and functioning may contribute to obesity-related metabolic disorders and adverse health outcomes. Specific fat depots are suggested to possess unique biological properties, but specific metabolic profiles of subcutaneous (SAT) and visceral adipose tissue (VAT) remain unknown. We aimed to characterize VAT and SAT glucose metabolism, and their relationship with body mass index (BMI). AT samples from patients (n = 12; F:M, 9:3) with a mean age of 46 years (26–83 years) and an average BMI of 29.6 kg/m\textsuperscript{2} (18–37 kg/m\textsuperscript{2}) were used. VAT and SAT explants were obtained during elective laparoscopy, either cholecystectomy for uncomplicated cholelithiasis or gastric bypass for severe obesity. Explants were placed in insulin-free cell culture media and their metabolic profiles were classically attributed to increased rates of lipolysis and release of free fatty acids into the bloodstream and liver portal circulation, which would then have a negative impact on hepatic insulin sensitivity\textsuperscript{[7]}.

1. Introduction

Metabolic homeostasis depends on adipose tissue (AT) functioning. AT stores energy that can be mobilized as needed and thus, it is considered a dynamic organ with a crucial role in the pathophysiology of dysmetabolism. AT has a strong influence in glucose and lipid metabolism as well as in systemic insulin sensitivity [1]. Regional fat distribution and functioning are likely to contribute to the link between obesity, metabolic disorders and health outcomes [2–4]. Metabolic activity of visceral adipose tissue (VAT) is associated with dyslipidemia, whereas subcutaneous adipose tissue (SAT) is reported to play a pivotal role for glucose and insulin homeostasis [5]. SAT and VAT differ in the basal antioxidant status and the antioxidant response capacity during obesity [6]. In addition, excess accumulation of VAT is associated with increased risk of several health complications, including diabetes, cardiovascular disease and mortality. These deleterious effects of VAT were classically attributed to increased rates of lipolysis and release of free fatty acids into the bloodstream and liver portal circulation, which would then have a negative impact on hepatic insulin sensitivity [7]. On the other hand, SAT appears to be relatively benign or even beneficial to health in some cases [8]. Using rodent models, it was shown that the transplantation of SAT to visceral locations can improve

glucose metabolism and insulin sensitivity [9], illustrating that both tissues have very distinct properties from a metabolic point of view.

Excess of adipose tissue contributes to the onset and deleterious effects promoted by obesity, but distinct adipose compartments present distinct anatomic distribution, cellularity patterns and molecular functioning. In adults, > 80% of total body fat is distributed in the subcutaneous compartment while only 10 to 20% is thought to be VAT [10]. Human SAT and VAT are reported to distinctly contribute to metabolic complications. VAT has an important role in the establishment of obesity-associated health problems due to its privileged localization to portal circulation and its secretory function of key bioactive substances [11,12]. Reducing VAT by omentectomy combined with gastric banding was also reported to have positive long-term effects on insulin sensitivity and glucose metabolic profiles of obese patients [13]. In humans, VAT is usually described as less stable and with a higher metabolic rate than SAT [14]. In addition, VAT was reported to possess higher content in metabolites involved in primary metabolism, including amino acids, carbohydrates or organic acids, while SAT was more rich in free fatty acids [15].

Though it has emerged that specific fat depots have unique biological and metabolic properties [16–18], the detailed metabolic differences between SAT and VAT remain largely unknown. To characterize the metabolic functioning of VAT and SAT and how it correlates with body mass index (BMI) is crucial to understand the pathogenesis of metabolic disorders in humans. Herein, we propose to determine VAT or SAT depots metabolism, and establish a correlation with BMI. With that purpose, paired samples of VAT and SAT tissue explants from patients undergoing elective cholecystectomy or laparoscopic gastric bypass for the treatment of obesity, respectively. Collection of tissue samples was performed after approval by the Local Ethics Committee and in accordance with the Guidelines of the Local, National and European Ethical Committees. All studies followed the Declaration of Helsinki for Medical Research involving Human Subjects. Patients (n = 12), were predominantly females (F:M, 9:3), with an average age of 46.8 years (range 26–83 years, mean) and an average body mass index (BMI) of 29.6 kg/m² (ranging from 18 to 37 kg/m²).

2. Material and methods

2.1. Chemicals

Fetal Bovine Serum (FBS) was purchased from Gibco (Life Technologies, Grand Island, NY, USA). Phenol-red free DMEM-F12, Penicillin-streptomycin (Pen-Strep) and all other chemicals were purchased from Sigma-Aldrich (St. Louis, MO, USA) unless otherwise specified.

2.2. Subjects

Abdominal subcutaneous and omental visceral human adipose tissue samples were collected during elective surgeries performed at Centro Hospitalar de Entre o Douro e Vouga, E.P.E, from patients without active infectious or neoplastic diseases, undergoing elective cholecystectomy or laparoscopic gastric bypass for the treatment of uncomplicated cholelithiasis or obesity, respectively were cultured in the absence of insulin and their metabolic profile was established.

2.3. Isolation and incubation of adipose tissue explants

Adipose tissue fragments from visceral and subcutaneous fat depots were collected under sterile conditions, placed in containers and subjected to identical handling. In brief, any blood and macroscopically visible damaged tissue were mechanically removed before tissue weighing. Adipose tissue fragments with similar weights were then acclimatized in fresh DMEM/F12 medium, at 37 °C, with 5% of CO₂, for 1 h. Then, culture media was replaced by fresh DMEM/F12 media with 1% Penicillin-streptomycin without FBS. After 72 h, the explant culture media was collected for secretome metabolic analysis and the tissue was weighed.

2.4. Proton nuclear magnetic resonance (1H NMR)

The metabolite content of culture media at the end of each incubation period was determined by 1H NMR, as previously described [19]. Sodium fumarate at a final concentration of 1 mM was used as an internal reference (6.50 ppm) to quantify the following metabolites (multiplet, ppm): H1-α glucose (doublet, 5.22), pyruvate (singlet, 2.38), acetate (singlet, 1.9), alanine (doublet, 1.44) and lactate (doublet, 1.33 ppm). The relative areas of 1H NMR resonances were quantified using the curve-fitting routine supplied with the NUTSpro NMR spectral analysis program (Acorn NMR, Livermore, CA, USA). Results are expressed as nanomoles of metabolite consumed (or produced) per milligram of wet tissue.

2.5. Statistical analysis

Table 1

| Metabolites | Visceral | Subcutaneous |
|-------------|----------|--------------|
| Glucose (C) | 246 ± 77 | 254 ± 63     |
| Pyruvate (C)| 12 ± 3   | 15 ± 3       |
| Alanine (P) | 5 ± 1    | 8 ± 2        |
| Acetate (P) | 19 ± 7   | 24 ± 7       |
| Lactate (P) | 59 ± 11  | 86 ± 13      |

Table 2

| Metabolites (nmol/mg of wet tissue) | Visceral | Subcutaneous |
|------------------------------------|----------|--------------|
| Glucose (C)                        | 246 ± 77 | 254 ± 63     |
| Pyruvate (C)                       | 12 ± 3   | 15 ± 3       |
| Alanine (P)                        | 5 ± 1    | 8 ± 2        |
| Acetate (P)                        | 19 ± 7   | 24 ± 7       |
| Lactate (P)                        | 59 ± 11  | 86 ± 13      |
3. Results

3.1. Patients serum biochemical profile

Abdominal subcutaneous and omental visceral human adipose tissue samples were collected from patients undergoing elective cholecystectomy or laparoscopic gastric bypass for the treatment of gallbladder lithiasis or obesity, respectively. The group of individuals selected presented a homogeneous serum biochemical profile, as seen in Table 1.

3.2. Human subcutaneous and visceral adipose tissue explants presented a similar metabolic profile in culture

Our data showed that glucose consumption was similar in both, VAT and SAT, which present a consumption of 246 ± 77 nmol/mg of wet tissue and 254 ± 63 nmol/mg of wet tissue, respectively (Table 2).

table 3

|                    | Visceral adipose tissue | Subcutaneous adipose tissue |
|--------------------|-------------------------|-----------------------------|
|                    | Alanine (P)             | Acetate (P)                 | Lactate (P) |
| Glucose (C)        | ↓                      | NS                          | 0.639       |
| Pyruvate (C)       | ↓                      | NS                          | 0.948       |

Legend: R values are Pearson’s correlation coefficient for: *P < 0.05; **P < 0.005; ***P < 0.001. (C) – metabolite consumption; (P) – metabolite production; NS – non-significant.

3.3. Region-dependent association of glucose and pyruvate consumption by adipose tissue explants with acetate production

Our results showed that acetate production by cultured explants of VAT was positively correlated with glucose (R = 0.639; p < 0.05) and VAT consumed 12 ± 3 nmol/mg of wet tissue of pyruvate, which was very similar to SAT that consumed 15 ± 3 nmol/mg of wet tissue (Table 2). Pyruvate is the end-product of glycolysis and can be used to either fuel mitochondria or to be converted to alanine or lactate. There was no significant increase on lactate production in SAT (86 ± 13 nmol/mg of wet tissue) when compared with VAT (59 ± 11 nmol/mg of wet tissue). The alanine production was also very similar in both tissues (Table 2). Short chain fatty acids, such as acetate, have important physiological roles in adipogenesis [20]. Our results showed that acetate production was 19 ± 7 nmol/mg of wet tissue in VAT and 24 ± 7 nmol/mg of wet tissue in SAT (Table 2).
3.4. Increased glucose consumption by VAT, but not by SAT, was positively associated with the BMI of the patients

Our data showed that glucose consumption by explants of VAT was positively correlated with the BMI of the patients \( r = 0.593, p < 0.05 \) (Fig. 1A), illustrating that VAT explants collected from patients with higher BMI consumed more glucose than those collected from patients with lower BMI. Furthermore, this effect was observed in the absence of insulin and was thus independent of the glucose uptake mediated by the hormone. However, there was no correlation between pyruvate consumption by VAT explants and the patients BMI (Fig. 1C). Our data also showed that glucose and pyruvate consumption by SAT was independent of the patients BMI, illustrating that the metabolic functioning of this tissue is not affected by the BMI of the patients (Fig. 1B,D).

3.5. Secretome of SAT is not affected by the BMI of the patients but VAT production of alanine and lactate is negatively correlated with the patients BMI

Acetate production by both, VAT and SAT, was not correlated with the BMI of the patients (Fig. 2A, B). However, the production of alanine by VAT was negatively correlated \( r = -0.629, p < 0.05 \) with the patients BMI illustrating that alanine production was decreased in VAT of patients with higher BMI (Fig. 2C). Lactate production by VAT was also negatively correlated \( r = -0.688, p < 0.05 \) with the patients BMI.

Fig. 2. Substrate production by cultured visceral (VAT) and subcutaneous (SAT) adipose tissue. The figure shows acetate, alanine and lactate production by VAT (panels A, C, E) and SAT (panels B, D, F) of patients \( n = 12, F:M, 9:3 \) with an average age of 46.8 years (range 26–83 years, mean) and different body mass index (BMI). The association between metabolite production and BMI was evaluated by computing Pearson correlation coefficients \( r \) assuming Gaussian distribution and a confidence interval of 95%. All \( P \) values < 0.05 were considered statistically significant.

Our data showed that glucose consumption by cultured explants of VAT with alanine or lactate production (Table 2). In addition, cultured explants of SAT only presented a positive correlation between pyruvate consumption and acetate production \( R = 0.804; p < 0.005 \). No other correlation was detected between the other metabolites studied in the secretome of cultured SAT (Table 3).

pyruvate consumption \( R = 0.948; p < 0.001 \). No correlations were detected between glucose or pyruvate consumption by cultured explants of VAT with alanine or lactate production (Table 2). In addition, cultured explants of SAT only presented a positive correlation between pyruvate consumption and acetate production \( R = 0.804; p < 0.005 \). No other correlation was detected between the other metabolites studied in the secretome of cultured SAT (Table 3).
BMI (Fig. 2E). On the other hand, the production of acetate, alanine or lactate of SAT remains independent of the patients BMI (Fig. 2B, D, F). Overall, these results show that the metabolic behavior of VAT, but not SAT, in culture is dependent of the patients BMI.

4. Discussion

Adipose tissue undergoes dynamic remodeling in response to several nutritional and metabolic cues. Those alterations can be region-dependent and provide key information concerning distinguishing severity of obesity to health. Despite several differences have been described in the physiological properties of SAT and VAT, our results show that the two regional adipose tissue deposits appear to have a similar glucose metabolic profile when directly compared without considering the BMI of the patients. However, when we correlate the metabolic profile of VAT and SAT with the patient's BMI, our results show that BMI promotes a metabolic reprogramming of adipose tissue, particularly in the glycolytic profile of VAT, towards an increase in de novo lipogenesis. As this metabolic profiling was performed in the absence of insulin, which is known to have an important role in stimulating the cell glucose uptake, these preliminary results highlight that the metabolic reprogramming may occur beyond the effects known to be mediated by insulin. Visceral obesity is tightly connected with increased insulin resistance and secondary hyperinsulinism that are believed to have an important role in the metabolic shift experienced by obese patients. Thus, targeting insulin resistance and hyperinsulinism has been the mainstay to correct obesity related metabolic imbalance. What our data highlights is that beyond the effects that are known to be driven by insulin mediated pathways, there could be additional routes leading to the observed metabolic shifts, independent of hyperinsulinemia or insulin resistance.

Epidemiologic studies show that excess of VAT is more closely correlated with the development of metabolic disorders, such as type 2 diabetes and the metabolic syndrome, than excess of SAT [21]. One of the commonly accepted explanations for this observation is that the two fat depots appear to have different glucose metabolic profiles when directly compared without considering the BMI. However, when we correlate the metabolic profile of VAT and SAT with the patient's BMI, our results show that BMI promotes a metabolic reprogramming of adipose tissue, particularly in the glycolytic profile of VAT, towards an increase in de novo lipogenesis. As this metabolic profiling was performed in the absence of insulin, which is known to have an important role in stimulating the cell glucose uptake, these preliminary results highlight that the metabolic reprogramming may occur beyond the effects known to be mediated by insulin. Visceral obesity is tightly connected with increased insulin resistance and secondary hyperinsulinism that are believed to have an important role in the metabolic shift experienced by obese patients. Thus, targeting insulin resistance and hyperinsulinism has been the mainstay to correct obesity related metabolic imbalance. What our data highlights is that beyond the effects that are known to be driven by insulin mediated pathways, there could be additional routes leading to the observed metabolic shifts, independent of hyperinsulinemia or insulin resistance.

Fig. 3. Schematic representation of the studied metabolic pathways in adipose tissue explants, visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT). We focused on glucose metabolism independent from insulin stimuli. Our results show that tissue explants of VAT from patients with higher BMI consumed more glucose and produced less metabolites directly derived from pyruvate (e.g. lactate and alanine) and maintained the same production of acetate. Thus, we suggest that with the increase of BMI, VAT reprograms glucose metabolism towards de novo lipogenesis. Thus, our results provide a preliminary evidence that increased BMI promotes an insulin-independent metabolic reprogramming of glucose metabolism in VAT that may be associated with increased de novo lipogenesis. (AATs-Aminoacid transporters; Ins-Dep GLUTs-Insulin dependent glucose transporters; Ins-Ind GLUTs-Insulin independent glucose transporters; MCTs-Monocarboxylic acid transporters; IR-Insulin receptors).
mechanism by which dietary fat competes with carbohydrates for storage as triglycerides in adipose tissue [31]. Our results provide clear evidence that in absence of insulin cultured VAT, but not SAT, increases the consumption of glucose, followed by a decrease in the production of lactate and alanine, illustrating that it may be redirected to de novo lipogenesis. Our results show that VAT is a metabolically active tissue that responds to BMI and extracellular glucose concentration. Tissue explants of VAT from subjects with higher BMI presented an insulin-independent metabolic reprogramming of glucose metabolism that may be associated with increased de novo lipogenesis, for all other metabolic routes evaluated were not found to be stimulated (summarized in Fig. 3), particularly lactate, alanine and acetate production. This suggests that several obesity-related metabolic shifts usually attributed to insulin action may be due to the metabolic adaptations of the tissue induced by the subjects BMI beyond insulin mediated effects. Further studies will be needed to test this hypothesis. The use of paired explants of VAT and SAT reflects a more physiological in vivo function since the tissue is relatively intact and there is no selective loss of certain types of adipocytes. Besides, it avoids the use of mechanical and/or biological digestions to isolate cells, which may alter the metabolic behavior of cells. However, the use of homogeneous preparations of isolated adipocytes may help to further understand the non-insulin mediated metabolic reprogramming of VAT during the increase of the subjects BMI.

In conclusion, our preliminary results show that BMI is associated with region-dependent metabolic reprogramming towards de novo lipogenesis in VAT and suggest that insulin action may not be required for the deleterious metabolic remodeling of VAT. Nevertheless, this data is still preliminary and studies are required to further test this hypothesis and to understand the role of insulin and the molecular mechanisms underlying this metabolic reprogramming. Adipocyte is gaining attention as a central rheostat of systemic and localized energy homeostasis. Identification of the molecular mechanisms underlying VAT and SAT metabolic behavior, which promote lipid accumulation and VAT expansion in detriment of the more physiological and less detrimental lipid storage in the peripheral SAT, harbors the potential of disclosing novel molecular targets that could be used to counteract obesity related metabolic co-morbidities.
