(Dated: September 17, 2009)

We apply the unbiased weak-coupling continuous time quantum Monte Carlo (CTQMC) method to review the physics of a single magnetic impurity coupled to s-wave superconducting leads described by the BCS reduced Hamiltonian. As a function of the superconducting gap \( \Delta \), we study the signature of the first order transition between the singlet and doublet (local moment) states on various quantities. In particular we concentrate on the Josephson current with 0 to \( \pi \) phase shift, the crossing of the Andreev bound states in the single particle spectral function, as well as the local dynamical spin structure factor. Within DMFT, this impurity problem provides a link to the periodic Anderson model with superconducting conduction electrons (BCS-PAM). The first order transition observed in the impurity model is reproduced in the BCS-PAM and is signalized by the crossing of the low energy excitations in the local density of states. The momentum resolved single particle spectral function in the singlet state reveals the coherent, Bloch-like, superposition of Andreev bound states. In the doublet or local moment phase the single particle spectral function is characterized by incoherent quasiparticle excitations.

I. INTRODUCTION

Magnetic degrees of freedom in superconducting environments have attracted considerable interest due to the underlying competing effects. Already a classical spin oriented along the \( z \)-axis [1,2] embedded in a superconducting host generates a localized state within the superconducting gap. As a function of the interaction strength this excitation crosses the Fermi energy thereby triggering a first order transition between a ground state with vanishing total electronic spin and a ground state with nonzero total electronic spin.

For a quantum spin, the Kondo effect sets in. Being a Fermi surface instability, the opening of the superconducting gap competes with Kondo screening and ultimately leads to a local moment regime. This transition is accompanied by a 0 to \( \pi \) phase shift in the Josephson current. In the local moment regime the \( \pi \)-shift occurs since a Cooper pair tunneling through the junction necessarily accumulates a phase \( \pi \).

The interest in the problem has been renewed in the last decade by the rapid progress in nanotechnology which made a direct experimental realization of quantum dots coupled to superconducting leads feasible so that many experiments have been designed to directly measure the 0 to \( \pi \) transition of the Josephson current. Experiments using a carbon nanotube [3,4] but also InAs nanowires [5,6] as a quantum dot coupled to superconducting leads were able to observe the sign change of the Josephson current by increasing the gate voltage and thus manipulating the number of electrons on the quantum dot. The effect of the changing electron number on the behavior of such systems has been extensively studied [3,4,13,14,26] and the theoretical expectation of the collapse of the Kondo effect if the superconducting gap \( \Delta \) exceeds the Kondo temperature \( T_K \) has been confirmed by experiments of Buitelaar et al. [15].

From the numerical point of view, a combination of algorithmic development and computational power has allowed for a more detailed study of the problem using the numerical renormalization group [16,17,18,19,20] quantum Monte Carlo simulations [20,21,22] as well as functional renormalization group calculations [21]. Most numerical works present in the literature only present either the study of the Josephson current [15,13,20,21,23] or the study of the spectral properties of the Quantum dot [13]. One of the goals of this article is to use the weak coupling CTQMC method [21] to compute the Josephson current as well as the spectral functions for the same parameter set in order to present a comprehensive study of the 0 to \( \pi \) transition of a Josephson quantum dot. Our numerically exact data clearly confirms the picture of a first order phase transition from a singlet phase linked to the 0-junction regime of the Josephson current to a doublet phase corresponding to the \( \pi \)-junction regime.

In addition to numerical efforts, many analytical approximations have been introduced to tackle different aspects of the physics of the problem. The non crossing approximation has been used to show that Andreev bound states crossing the Fermi energy are connected to the 0 to \( \pi \) transition of the Josephson current [20]. Perturbative methods as well as mean field theory have brought a quite complete understanding of the phase diagram featuring the 0 and \( \pi \) phases as well as the intermediate phases 0' and 2\( \pi \) [20,21,23]. Another method employed by several authors is the introduction of different analytically solvable effective models, which are valid in different limits [13,14,21,23]. These models are very useful to acquire an intuitive understanding of the physics. We will present the study of an effective Hamiltonian for the limit of a superconduct-
ing gap $\Delta$ much larger than the bandwidth to support the interpretation of the CTQMC data.

Another motivation of this paper, is to study within dynamical mean field theory (DMFT) the periodic Anderson model with an s-wave BCS-conduction band (BCS-PAM). Within this approximation, the BCS-PAM maps onto the single impurity Anderson model with superconducting baths supplemented with a self-consistency condition. We will show that the physics of the impurity model can be taken over to the lattice case. In particular the first order transition observed in the impurity model is reproduced in the BCS-PAM and is signalized by the crossing of the low energy excitations in the local density of states. The momentum resolved single-particle spectral function in the singlet phase reveals the coherent, Bloch-like, superposition of Andreev bound states. In the doublet or local moment phase the single particle spectral function is characterized by incoherent quasiparticle excitations. We provide an understanding of this in terms of models of disorder.

The paper is organized as follows. After introducing the model in Sec. II we discuss in Sec. III an effective toy model valid in the limit of a superconducting gap, $\Delta$, much larger than the bandwidth $W$. This simple toy model gives a good way at understanding certain aspects of the underlying physics. A brief outline of the employed CTQMC result including the proof of Wick’s theorem for each configuration in the Monte Carlo simulation will be presented in Sec. IV. The results of the toy model are then compared to the results of the CTQMC simulation, which are discussed in detail in Sec. V. Sec. VI is dedicated to the study of the BCS-PAM within DMFT. We include an appendix featuring the proof of a general determinant identity needed for the proof of Wick’s theorem for every configuration in the CTQMC.

II. MODEL

The physics of a quantum dot coupled to two superconducting leads (L=left, R=right) via a hybridization term is captured by the single impurity Anderson model with the leads described by the BCS mean-field Hamiltonian:

$$H = \sum_{\alpha=L}^{R} \tilde{H}_0 + \tilde{H}_d + \tilde{H}_V,$$

with

$$\tilde{H}_0 = \sum_{k,\sigma} \xi_k \tilde{c}_{k,\sigma}^\dagger \tilde{c}_{k,\sigma} + \sum_{k} \left( \Delta \epsilon_{\phi} \tilde{c}_{k,1,\sigma}^\dagger \tilde{c}_{-k,1,\sigma} + \text{h.c.} \right),$$

$$\tilde{H}_d = \sum_{\sigma} \epsilon_d \tilde{d}_{\sigma}^\dagger \tilde{d}_{\sigma} + U \left( \tilde{d}_{\uparrow}^\dagger \tilde{d}_{\uparrow} - \frac{1}{2} \right) \left( \tilde{d}_{\downarrow}^\dagger \tilde{d}_{\downarrow} - \frac{1}{2} \right),$$

$$\tilde{H}_V = -\frac{V}{\sqrt{N}} \sum_{\alpha=L}^{R} \sum_{\sigma, k} \left( \tilde{c}_{\alpha,\sigma}^\dagger \tilde{d}_{\sigma} + \tilde{d}_{\sigma}^\dagger \tilde{c}_{\alpha,\sigma} \right).$$

The operators $\tilde{c}_{k,\sigma,\alpha}$ are creation operators for electrons with a $z$-component of the spin $\sigma$ and momentum $k$ in lead $\alpha$, $\tilde{d}_{\sigma}$ is a creation operator of an electron with a $z$-component of the spin $\sigma$ on the quantum dot. $\xi_k = \epsilon(k) - \mu = -2t \cos(k) - \mu$ is the dispersion relation for the electrons in the leads, where we assume, that the dispersion is independent of the lead index $\alpha$, and $\xi_d = \epsilon_d - \mu$ is the position of the dot level. Throughout this paper, we will express all quantities in units of $t = 1$. The superconducting order parameter has a modulus $\Delta$ and a phase $\phi_\alpha$. The parameter $V$ characterizes the strength of the hybridization, and $U$ corresponds to the Coulomb blockade.

Since the Hamiltonian does not conserve the electron number as a consequence of the BCS-term, we use the standard trick of rewriting the Hamiltonian in terms of creation and annihilation operators of quasiparticles, which for spin up are identical to the electrons, but correspond to holes in the spin down sector. This can also be expressed as a canonical transformation:

$$\tilde{d}_{\uparrow}^\dagger \rightarrow \tilde{d}_{\uparrow}^\dagger, \quad \tilde{d}_{\downarrow}^\dagger \rightarrow \tilde{d}_{\downarrow}, \quad \tilde{c}_{k,\uparrow,\alpha}^\dagger \rightarrow \tilde{c}_{k,\uparrow,\alpha}^\dagger, \quad \tilde{c}_{-k,\downarrow,\alpha}^\dagger \rightarrow c_{k,\downarrow,\alpha}^\dagger.$$  \hfill (3)

Using the new operators, the Hamiltonian can be written in a Nambu notation:

$$H = H_0 + H_U = \sum_{k,\alpha} \epsilon_d c_{k,\alpha}^\dagger c_{k,\alpha} + d_{\sigma}^\dagger \epsilon_d d_{\sigma}$$

$$- \frac{V}{\sqrt{N}} \sum_{k,\alpha} \left( \epsilon_d c_{k,\alpha}^\dagger \sigma_{\sigma} d_{\sigma} + d_{\sigma}^\dagger \sigma_{\sigma} c_{k,\alpha} \right) + H_U$$

with $H_U = -U (d_{\uparrow}^\dagger d_{\uparrow} + \frac{1}{2}d_{\downarrow}^\dagger d_{\downarrow} - \frac{1}{2})$, the Nambu spinors

$$d = \left( \begin{array}{c} \tilde{d}_{\uparrow}^\dagger \\ \tilde{d}_{\downarrow} \end{array} \right), \quad c_{k,\alpha} = \left( \begin{array}{c} c_{k,\uparrow,\alpha} \\ c_{k,\downarrow,\alpha} \end{array} \right),$$

the matrices

$$E_{\alpha}(k) = \left( \begin{array}{cc} \xi_k & -\Delta \epsilon_{\phi} \\ -\Delta \epsilon_{\phi} & -\xi_k \end{array} \right), \quad \epsilon_d = \left( \begin{array}{cc} \xi_d & 0 \\ 0 & -\xi_d \end{array} \right),$$

and the Pauli matrix

$$\sigma_z = \left( \begin{array}{cc} 1 & 0 \\ 0 & -1 \end{array} \right).$$

For practical reasons, we use the following definition for the single particle Green’s function throughout Sec. II to Sec. VI

$$G^{\alpha\sigma}_{dd}(i\omega_m) = \beta \int_0^\beta \text{d} \tau \exp(i\omega_m \tau) \langle T d_{\sigma}^\dagger(t) d_{\sigma} \rangle.$$  \hfill (8)

With this definition, the resolvent operator $G^{0}(i\omega_m) = (-i\omega_m 1 - H^{0})^{-1}$ can be used to obtain the Green’s function of the noninteracting system:

$$G^{0}_{dd}(i\omega_n)^{-1} = (-i\omega_n 1 - \epsilon_d)$$

$$+ \frac{V^2}{N} \sum_{\alpha,k} \sigma_z \left( i\omega_n 1 + B_{\alpha}^T(k) \right)^{-1} \sigma_z.$$  \hfill (9)
III. EFFECTIVE HAMILTONIAN IN THE LIMIT $\Delta/W \to \infty$

To gain a deeper understanding of the physics on the quantum dot, it is useful to search for analytically solvable toy models. We will study an effective model, which reproduces the physics of the Hamiltonian (1) in the limit $\Delta/W \to \infty$, where $W$ is the band width. To derive the effective model, we look at the limit $\Delta \to \infty$ of the Green’s function in Eq. (9). The superconducting order parameter $\Delta$ appears only in the matrix $E_\alpha(k)$, thus we examine the behavior of this matrix for large values of $\Delta$. This can easily be done by diagonalizing $E_\alpha(k)$ for $\alpha = 0$:

$$E_\alpha(k) = U_{\Delta}^{-1} \left( \begin{array}{cc} -\Delta^2 + \xi_k & \xi_k \\ 0 & \sqrt{\Delta^2 + \xi_k^2} \end{array} \right) U_{\Delta}. \quad (10)$$

Let us first look at the limit $\Delta \to \infty$ of the transformation matrix $U_{\Delta}$, for which brevity is not a unitary matrix.

$$U_{\Delta} = \left( \begin{array}{cc} -\xi_k + \sqrt{\Delta^2 + \xi_k^2} & 1 \\ -\xi_k - \sqrt{\Delta^2 + \xi_k^2} & 1 \end{array} \right) \Rightarrow U_{\infty} = \left( \begin{array}{cc} 1 & 1 \\ -1 & 1 \end{array} \right). \quad (11)$$

The diagonal matrix in Eq. (10) can be considered in a similar manner and we obtain for $\lim_{\Delta \to \infty} E_\alpha(k) = E_{\infty}$:

$$E_{\infty} = U_{\infty}^{-1} \left( \begin{array}{cc} 0 & -\Delta \\ -\Delta & 0 \end{array} \right) U_{\infty} = \left( \begin{array}{cc} 0 & -\Delta \\ -\Delta & 0 \end{array} \right). \quad (12)$$

Using this result, for large values of $\Delta$ the sum over $k$ and $\alpha$ in Eq. (9) can be carried out yielding

$$G_{dd}^{0,\infty}(i\omega_n)^{-1} = (-i\omega_n 1 - \epsilon_d) + 2V^2 \sigma_z (i\omega_n 1 + E_{\infty})^{-1} \sigma_z. \quad (13)$$

This is exactly the free Green’s function obtained from a Hamiltonian of the form:

$$H_{\text{eff}} = -\sqrt{2}V (c^\dagger \sigma_z d + d^\dagger \sigma_z c) + c^\dagger E_{\infty} c + d^\dagger \epsilon_d d + H_U. \quad (14)$$

$H_{\text{eff}}$ describes a system consisting of one bath site $c$ connected by a hybridization term to the correlated quantum dot $d$. The dispersion of the bath has completely vanished, as the superconducting band gap becomes much larger than the bandwidth.

We chose a basis of the 16 dimensional Hilbert space and write the Hamiltonian as a matrix, which subsequently can be diagonalized. As we have restricted the parameter space for the Monte Carlo simulations to $\epsilon_d = 0$ and $\mu = 0$ in the original Hamiltonian of Eq. (1), we will use the same parameters for the exact diagonalization results.

A. Ground state of the effective model

The ground state of the system (14) can be determined by diagonalizing the Hamiltonian $H_{\text{eff}}$. As depicted in Fig. 1, the energy levels cross at a critical value of $U = U_c$ and a similar behavior can be observed by varying $\Delta$ with a corresponding critical value $\Delta_c$. For $U < U_c$ and $\Delta < \Delta_c$, the ground state is given by $|\psi_\alpha\rangle = -\alpha (|\uparrow\downarrow, 0\rangle - |0, \uparrow\downarrow\rangle) - \beta (|\uparrow\downarrow, \uparrow\downarrow\rangle + |\downarrow\uparrow, \uparrow\downarrow\rangle) - \gamma (|\downarrow\downarrow, \uparrow\downarrow\rangle + |\uparrow\downarrow, \downarrow\uparrow\rangle)$, with the notation $c_\alpha^\dagger |0, 0\rangle = |\sigma, 0\rangle$ and $d_\alpha^\dagger |0, 0\rangle = |0, \sigma\rangle$. Note, that we are using the unphysical basis introduced in Eq. (3). To interpret this ground state it is better to return to the physical basis by inverting the canonical transformation in Eq. (3) and transforming the vacuum state $|0, 0\rangle \to |\downarrow, \downarrow\rangle$. The ground state can then be rewritten in the physical basis.
A. Effective model

The effective model is shown in Fig. 3. At low temperature the double occupancy $\langle |\uparrow\downarrow\rangle$ of the total spin $\pm$ is given by

$$\langle |\uparrow\downarrow\rangle = a \left( |\uparrow\uparrow\rangle - |\downarrow\downarrow\rangle \right) + \beta \left( |\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle \right) + \gamma \left( |\uparrow\uparrow\rangle + |\downarrow\downarrow\rangle \right).$$

(15)

This state is clearly a singlet state, corresponding to a Kondo singlet between the quantum dot and the bath with the dominant weight $\alpha$. The states representing a pairing on the quantum dot or in the bath have the suppressed weights $\beta$ and $\gamma$ for small values of $\Delta$ but grow more important if $\Delta$ is increased as is shown in Fig. 2.

At $U > U_c$, the ground state changes and we get the two-fold degenerate ground states $|\psi_{d,1}\rangle = a (|\uparrow\uparrow\rangle - |\downarrow\downarrow\rangle) + b (|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)$ and $|\psi_{d,1}\rangle = a (|0\uparrow\rangle - |0\downarrow\rangle) + b (|1\downarrow\rangle + |1\uparrow\rangle)$, rewritten in the physical basis:

$$|\psi_{d,1}\rangle = a \left( |\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle \right) + b \left( |\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle \right).$$

(16)

This two-fold degenerate ground state has a $z$-component of the total spin $\pm 1/2$ and hence corresponds to a local moment.

B. Phase diagram

To further illustrate the phase transition between the singlet state $|\psi_s\rangle$ and the doublet states $|\psi_{d,1}\rangle$, the double occupancy $\langle \tilde{d}_1^\dagger \tilde{d}_1 \tilde{d}_1^\dagger \rangle$ of the quantum dot in the effective model is shown in Fig. 3. At low temperature a very sharp drop of the double occupancy on the phase boundary can be observed, which evolves to a jump at $T = 0$. Here the larger values of the double occupancy are connected to the singlet phase, while the lower values belong to the doublet phase, where single occupancy is favored. This can be understood by studying the expectation value of the double occupancy in the ground state.

In the singlet phase, we obtain

$$\langle \psi_s | \tilde{d}_1^\dagger \tilde{d}_1 | \psi_s \rangle = |a|^2,$$

and for the doublet phase,

$$\langle \psi_{d,1} | \tilde{d}_1^\dagger \tilde{d}_1 | \psi_{d,1} \rangle = |\alpha|^2.$$

(17, 18)

From the behavior of the weights $\beta$, $\gamma$ and $a$ shown in Fig. 2, it is clear that the double occupancy increases with $\Delta$ in the singlet phase and decreases in the doublet phase.

Note, that many of the results presented in this paper can be observed either at fixed $U$ or $\Delta$ as can be conjectured from Fig. 3.

C. Proximity effect

To gain further insight in the sign change of the local pair correlations $\langle \tilde{d}_1^\dagger \tilde{d}_1 \rangle$, we calculate the ground state expectation value of the local pair correlations in the effective model [14]. For the singlet phase, we obtain

$$\langle \psi_s | \tilde{d}_1^\dagger \tilde{d}_1 | \psi_s \rangle = \langle \psi_s | \left( \beta |\uparrow\downarrow\rangle \right) \langle \uparrow\downarrow | + \gamma |\uparrow\downarrow\rangle \right) \right) + 2\text{Re}(\beta^* \gamma) \geq 0.$$

(19)

Clearly, only terms describing the pairing on the quantum dot contribute to the pair correlations, whereas the Kondo singlet of electrons on the quantum dot and in the bath does not. From Fig. 2 it is obvious that the resulting pairing correlation is positive and increases with $\Delta$. This illustrates the proximity effect, as a pair field in the bath induces a pair field on the quantum dot.

On the other hand, in the doublet phase, we obtain

$$\langle \psi_{d,1} | \tilde{d}_1^\dagger \tilde{d}_1 | \psi_{d,1} \rangle = \langle \psi_{d,1} | a |\uparrow\downarrow\rangle \right) \langle \uparrow\downarrow | - |\uparrow\downarrow\rangle \right) \right) = -|\alpha|^2 < 0.$$

(20)

As in the singlet phase, only the states corresponding to a pairing on the quantum dot contribute to the pair correlations. The local moment part of the ground state does not generate pair correlations. As the weight $a$ in the doublet phase ground state is positive and decreases with $\Delta$ (see Fig. 3), the local pair correlations have a negative sign in contrast to the positive sign in the singlet phase and decrease with $\Delta$.

D. Spectral function

Using the Lehmann representation, the spectral function $A_{\uparrow\downarrow}(\omega)$ of the effective model is easily calculated. It
is defined by

\[ A_{\uparrow \uparrow}(\omega) = \frac{\pi}{Z} \sum_{n,m} M_{nm} (e^{-\beta E_n} + e^{-\beta E_m}) \delta(\omega + E_n - E_m), \tag{21} \]

with the matrix elements \( M_{nm} = |\langle n | \hat{d}_z^\dagger | m \rangle|^2 \). The spectral function is shown in Fig. 4. Comparing this plot to the numerical solution of the full model as depicted in Fig. 14, we observe, that the simple model already shows the important feature of an excitation at the position \( \omega = 0 \) at the critical value of \( \Delta \). Even though for very small values of \( \Delta \), the Kondo resonance at \( \omega = 0 \) can not be seen in the simple model, we see a precursor of the Kondo resonance as a pole of the Green’s function, which develops into a resonance if we increase the number of sites in the bath.\[ \text{[22]} \]

A careful analysis reveals, that the low frequency signature of the spectral function reflects the excitation between the two lowest lying states of the spectrum. These states are the ground states of the singlet and the doublet phase and therefore, the position \( \omega \) of the excitation marks precisely the energy difference of the two ground states. At the critical value of \( \Delta = 1.412 \), the level crossing occurs and leads to a vanishing energy difference of the two ground states, meaning that the excitation between the two states lies now precisely at \( \omega = 0 \).

### E. Dynamical spin structure

Like the spectral function, the dynamical spin structure factor \( S(\omega) \) can be calculated using the Lehmann representation:

\[ S(\omega) = \frac{\pi}{Z} \sum_{n,m} e^{-\beta E_n} \left| \langle n | \hat{S}_z \hat{S}_z | m \rangle \right|^2 \delta(\omega + E_n - E_m). \tag{22} \]

In the Monte Carlo simulation, a numerically more stable quantity is obtained by replacing \( \hat{S}_+ \) by \( \hat{S}_z \) in the above equation. This quantity is completely equivalent to \( S(\omega) \), as we only make use of the \( SU(2) \)-symmetry of the problem, and is therefore used in the following.

In the representation \( S(\omega) \), it is clear that the dynamical spin structure factor will show excitations at frequencies corresponding to the energy needed to flip the spin on the quantum dot. Therefore, the dynamical spin structure factor is very well suited to determine whether the system is in the singlet or in the doublet regime.

In Fig. 5 the phase transition from the singlet phase to the doublet phase is reflected by the fact, that in the singlet phase, a gapped excitation can be observed, whereas in the doublet phase, a peak at \( \omega = 0 \) emerges, which corresponds to a local magnetic moment.

### F. Dynamical charge structure

The dynamical charge structure factor \( N(\omega) \) can be defined by the Lehman representation

\[ N(\omega) = \frac{\pi}{Z} \sum_{n,m} |\langle n | \hat{d}_z^\dagger \hat{d}_z | m \rangle|^2 e^{-\beta E_m} \delta(\omega + E_n - E_m). \tag{23} \]

As for the other spectral functions, the charge structure factor \( N(\omega) \) shown in Fig. 6 exhibits a sharp change of its behavior at the phase transition for the critical
value of the superconducting gap $\Delta$. We observe, that the charge structure shows a finite gap for all values of $\Delta$ and that for large values of $\Delta$, the gap increases in a slightly nonlinear manner.

A more detailed study of the matrix elements contributing to the charge structure factor reveals, that because of correlation we have completely different excitations than for the spectral function. In fact, the most prominent excitations are excitations from the respective ground states in the two different phases to higher energy states with structure similar to that of the ground states.

IV. CTQMC

A. Basic outline of the algorithm

For the numerically exact solution of the BCS-Anderson model, we used the weak coupling CTQMC-method, which is based on a perturbation expansion around the limit of $U = 0$. Following the presentation of the CTQMC-algorithm in the basic principles of the method.

As pointed out in the interacting Hamiltonian $H_U$ in Eq. (4) can up to a constant be rewritten as

\[
H_U = -\frac{U}{2} \sum_{\kappa=\pm 1} \left( d_\uparrow^{\dagger} d_\downarrow - \alpha_\kappa^* \right) \left( d_\downarrow^{\dagger} d_\uparrow - \alpha_\kappa \right)
\]

introducing the parameters $\alpha_\kappa^*$ to minimize the sign problem. For the present case, a choice of $\alpha_\uparrow^* = \alpha_\downarrow^* = \frac{1}{2} + s\delta$ with $\delta = \frac{1}{2} + 0^+$ was found to completely eliminate the sign problem at half filling, even after the complex phase factors $\exp(i\phi_\kappa)$ in the Hamiltonian were introduced.

Using perturbation theory, the partition function $Z$ of the full Hamiltonian $H$ can be written as:

\[
\frac{Z}{Z_0} = \langle T e^{-\int_0^\beta d\tau H_U(\tau)} \rangle_0 =
\]

\[
= \sum_{n=0}^{\infty} \left( \frac{U}{2} \right)^n \int_0^\beta d\tau_1 \ldots \int_0^{\tau_{n-1}} d\tau_n \sum_{s_1, \ldots, s_n} \times (25)
\]

\[
\times \langle \tau, \tau \rangle (\hat{n}_\uparrow(\tau_1) - \alpha_1^*) \ldots (\hat{n}_\downarrow(\tau_n) - \alpha_n^*) \rangle_0
\]

with the number operators $\hat{n}_\kappa = d_\kappa^{\dagger} d_\kappa$ and the thermal expectation value $\langle \cdot \rangle_0 = \frac{1}{Z} \text{Tr} \left[ e^{-\beta H_0} \cdot \right]$. As $H_0$ is a noninteracting Hamiltonian, Wick's theorem holds, and the expectation value $\langle T(\hat{n}_\uparrow(\tau_1) - \alpha_1^*) \ldots (\hat{n}_\downarrow(\tau_n) - \alpha_n^*) \rangle_0$ can be cast in a determinant of a matrix $M_C$, of size $2n \times 2n$, where $C_n$ is a configuration of the Hubbard model given in we do not need to include an index for the lattice site as we only have one correlated site, the impurity. The Matrix $M_C$ is not block diagonal for the two spin sectors in the case $\Delta \neq 0$, so we cannot factor the determinant in two determinants of $n \times n$ matrices. Finally, the partition function of the model is given by

\[
\frac{Z}{Z_0} = \sum_{C_n} \left( \frac{U}{2} \right)^n \det M_C
\]

where the sum runs over all possible configurations $C_n$ of vertices as $H$ The matrix $M_C$ is defined by

\[
M_C = \begin{pmatrix} G_{dd}(\tau_1, \tau_1) - \alpha_1 & \ldots & G_{dd}(\tau_n, \tau_1) \\ \vdots & \ddots & \vdots \\ G_{dd}(\tau_1, \tau_n) & \ldots & G_{dd}(\tau_n, \tau_n) - \alpha_n \end{pmatrix}
\]

using the $2 \times 2$ Green's function matrices $G_{dd}(\tau, \tau') = \langle \tau d_\downarrow(\tau) d_\uparrow(\tau') \rangle_0 \langle \tau d_\uparrow(\tau) d_\downarrow(\tau') \rangle_0$ and with $\alpha_i = \begin{pmatrix} \alpha_i^* \\ 0 \end{pmatrix}$. A similar reasoning yields an expression for the thermal expectation value $\langle O(\tau) \rangle = \frac{1}{Z} \text{Tr} \left[ e^{-\beta H} O(\tau) \right]$ of the full model:

\[
\langle O(\tau) \rangle = \sum_{C_n} \left( \frac{U}{2} \right)^n \det M_C \frac{\langle\langle O(\tau)\rangle\rangle_{C_n}}{\sum_{C_n} \left( \frac{U}{2} \right)^n \det M_C}
\]

Here $\langle\langle O(\tau)\rangle\rangle_{C_n}$ is the contribution of the configuration $C_n$ to the observable $O(\tau)$, which is given by

\[
\langle\langle O(\tau)\rangle\rangle_{C_n} = \frac{\langle \tau (\hat{n}_\uparrow(\tau_1) - \alpha_1^*) \ldots (\hat{n}_\downarrow(\tau_n) - \alpha_n^*) O(\tau) \rangle_0}{\langle \tau (\hat{n}_\uparrow(\tau_1) - \alpha_1^*) \ldots (\hat{n}_\downarrow(\tau_n) - \alpha_n^*) \rangle_0}
\]

Both, the numerator and the denominator of the above Eq. (26) can be written as determinants of matrices using Wick’s theorem. Eq. (28) is the central relation of the CTQMC algorithm, because starting from this equation, the Metropolis-Hastings-Algorithm can be employed to generate a Markov chain of configurations $C_n$. At this point, we have to interpret $\left( \frac{U}{2} \right)^n \det M_{C_n}$ as the statistical weight of a given configuration $C_n$ what in general
is impossible, as \( \det \mathbf{M}_{C_n} \) is a complex number. Therefore, we have to replace \( \left( \frac{1}{2} \right)^n \det \mathbf{M}_{C_n} \) by its modulus and account for the phase in the measurement of the observables. Fortunately, in the present case, the statistical weights are always real and nonnegative, so that we can simply calculate the contribution to the observable \( O(\tau) \) for a given configuration \( C_n \) in the Markov chain as \( \langle \langle O(\tau) \rangle \rangle_{C_n} \).

**B. Wick’s theorem for each configuration**

For the measurement of higher Green’s functions of the form \( \langle T \gamma_1^\dagger \gamma_1' \cdots \gamma_n^\dagger \gamma_n' \rangle \), where \( \gamma_i^\dagger \) stands for \( d_{n_i}(\tau_{i,\text{meas}}) \) or \( c_{n_i,\sigma_i,\alpha_i}(\tau_{i,\text{meas}}) \) depending on the quantity of interest, the calculation of the contribution \( \langle T \gamma_1^\dagger \gamma_1' \cdots \gamma_n^\dagger \gamma_n' \rangle_{C_n} \) is tedious and time consuming. Luckily for every configuration \( C_n \) a relation similar to Wick’s theorem can be found, which greatly simplifies the calculation of higher Green’s functions. It is closely connected to the determinant identity \( [A^2] \) proven in appendix A. The application of the ordinary Wick’s theorem to the denominator and the numerator of Eq. (29) yields

\[
\langle T \gamma_1^\dagger \gamma_1' \cdots \gamma_n^\dagger \gamma_n' \rangle_{C_n} = \frac{\det \mathbf{B}_{C_n}}{\det \mathbf{M}_{C_n}},
\]

where we have defined the matrix \( \mathbf{B}_{C_n} \in \mathbb{C}^{(2n+m)\times(2n+m)} \) as

\[
\mathbf{B}_{C_n} = \begin{pmatrix}
\mathbf{M}_{C_n} & \langle T \gamma_1^\dagger \mathbf{d}(\tau_1) \rangle_0 \\
\langle T \mathbf{d}(\tau_1) \gamma_1' \rangle_0 & \cdots & \langle T \mathbf{d}(\tau_n) \gamma_1' \rangle_0 \\
\vdots & \ddots & \vdots \\
\langle T \mathbf{d}(\tau_1) \gamma_n' \rangle_0 & \cdots & \langle T \mathbf{d}(\tau_n) \gamma_n' \rangle_0
\end{pmatrix},
\]

yielding

\[
\det \mathbf{B}_{C_n} = \left( \det \mathbf{M}_{C_n} \right)^n \left( \det \mathbf{B}_{C_n} \right)^m.
\]

From Eq. (29) it is obvious, that \( \det \mathbf{B}_{C_n} / \det \mathbf{M}_{C_n} \) is identical to the contribution of the configuration \( C_n \) to the one particle Green’s function \( \langle T \gamma_1^\dagger \gamma_1' \rangle \). Hence, Wick’s theorem holds for every configuration \( C_n \) and is given by

\[
\langle T \gamma_1^\dagger \gamma_1' \cdots \gamma_n^\dagger \gamma_n' \rangle_{C_n} = \det \begin{pmatrix}
\langle T \gamma_1^\dagger \gamma_1' \rangle_{C_n} & \cdots & \langle T \gamma_n^\dagger \gamma_n' \rangle_{C_n} \\
\vdots & \ddots & \vdots \\
\langle T \gamma_n^\dagger \gamma_n' \rangle_{C_n} & \cdots & \langle T \gamma_n^\dagger \gamma_n' \rangle_{C_n}
\end{pmatrix}.
\]

This relation is particularly useful in a simulation measuring multiple physical observables as measurements of single particle Green’s functions can be reused in an economic way.

**V. NUMERICAL RESULTS**

In this section, we present the results obtained by CTQMC simulations for the model \( [1] \). We restrict ourselves to the case of half filling, \( \epsilon_d = 0 \) and \( \mu = 0 \). In the first part of this section, we will discuss the results for static quantities including the Josephson current, double occupancy and pair correlations on the quantum dot. We then proceed to dynamical quantities such as the single particle spectral function and the dynamical spin structure factor.

**A. Josephson current**

The Josephson current flowing through the Quantum dot can be calculated directly within the CTQMC method, as it is given by an equal time Green’s function:

\[
\langle j_0 \rangle = \frac{i}{\sqrt{N}} \sum_{k,\sigma} \langle \tilde{e}_{k,\sigma,\alpha} \tilde{d}_{\sigma} - \tilde{d}_{\sigma}^{\dagger} \tilde{e}_{k,\sigma,\alpha} \rangle
\]

We show here our results for the Josephson current at an inverse temperature of \( \beta = 50 \) as a function of the su-
perconducting gap $\Delta$. For small values of $\Delta$, we observe a sinusoidal form of the Josephson current as a function of the phase difference $\phi$ with increasing amplitude, as $\Delta$ increases (see Fig. 7). For larger values of $\Delta$, the sign of the Josephson current changes and the grand potential shows now a single minimum at $\phi = 0$, this regime is therefore called the $\pi$ regime. (see Fig. 9).

This parameter regime is known as the 0-Junction regime, because the Josephson current $J_j(\phi) = \frac{\partial \Omega}{\partial \phi}$ has a zero with positive slope at $\phi = 0$, corresponding to a minimum in the grand potential $\Omega$ at $\phi = 0$ (see Fig. 5 in reference[23]).

If the value of $\Delta$ is further increased, the behavior of the Josephson current changes, as in the region $\Delta \approx 0.15 \ldots 0.35$ the Josephson current shows a zero between $\phi = 0$ and $\phi = \pi$. (see Fig. 8). This leads to a minimum in the grand potential at $\pi$ and the parameter regime is called $0'$ or $\pi'$ regime depending on which minimum of the grand potential is the global one[23]. The behavior of the Josephson current is in accordance with the behavior of the double occupancy seen in Fig. [12] as in the same parameter region, where we observe the $0'$ to $\pi'$ transition, the drop of the double occupancy as a function of $\phi$ can be observed, which is linked to the change of the curvature of the current-phase relation of the Josephson current.

For larger values of $\Delta$, the sign of the Josephson current changes and the grand potential shows now a single minimum at $\phi = \pi$, this regime is therefore called the $\pi$ regime. (see Fig. 9). The picture for the behavior of the grand potential as a function of $\phi$ that we get from the current phase relation of the Josephson current agrees very nicely with the results presented by Benjamin et al[35] and Karrasch et al. using the fRG and NRG methods[23]. Choi et al. using the Hirsch-Fye QMC method[20,21,22], as well as by Siano and Egger using the Hirsch-Fye QMC method[20,21,22]. Even though the numerical exactness of certain results has been debated, the results of all numerical works show very good qualitative agreement and are confirmed by the present results.

In the literature[23,21], the temperature dependence of the current phase relation of the Josephson current has been discussed. We show CTQMC results in Fig. 10 which look very similar to the Siano and Egger results[22]. As CTQMC is numerically exact, our result suggests that...
the crossing of all curves in one single point at $I_j = 0$ found in the approximate finite temperature NRG is not universal.

### B. Double occupancy

We learned from the toy model described in Sec. III that the system exhibits a phase transition from the singlet phase to the doublet phase as $U$ is increased. This picture is consistent with the NRG results of Bauer et al.\(^{13}\) The phase transition can be observed in the double occupancy $\langle \hat{n}_d \hat{n}_d \rangle$ of the quantum dot, which is proportional to $\frac{\partial U}{\partial \phi}$, where $\Omega$ is the grand potential. At $T = 0$, a sharp step function of the double occupancy is expected. While the $T = 0$ regime is not directly accessible to quantum Monte Carlo calculations, we calculated the double occupancy for different temperatures using the CTQMC-method. The results are shown in Fig. 11. From the data, it is obvious that with decreasing temperature the curves converge to the step function of the limit $T = 0$, which is a clear sign for a first order phase transition, reflecting a level crossing of the two ground states. This is in complete accordance with the results for the toy model.

It is interesting to correlate the Josephson current as a function of the phase difference $\phi = \phi_L - \phi_R$ for various values of $\Delta$ (see Sec. V A), with the double occupancy on the dot. As depicted in Fig. 12, for very small values of $\Delta$ (see Sec. V A), with the double occupancy on the dot. As depicted in Fig. 12, for very small values of $\Delta$ (see Sec. V A), with the double occupancy on the dot. As depicted in Fig. 12, for very small values of $\Delta$ (see Sec. V A), with the double occupancy on the dot.

The same qualitative behavior of the local pair correlation is also observed, if $U$ is changed instead of $\Delta$ as discussed in Sec. III C. We therefore conclude, that the sign change of the pair correlation is due to residual pairing on the quantum dot in the doublet phase which decreases with $\Delta$.

### C. Pair correlation

In agreement with the NRG result of Choi et al.\(^{16}\) as well as with the mean field results by Salkola et. al.\(^{19}\) we obtain the local pair correlation on the quantum dot shown in Fig. 13. For small $\Delta$, the local pair correlation increases because of the proximity effect, as an increasing magnitude of the pair field $\Delta$ in the leads induces a growing pair correlation on the quantum dot. The sharp sign change at the critical value of $\Delta$ observed at zero temperature is smeared out at finite temperatures, but the qualitative behavior is exactly the same as for the effective model discussed in Sec. III C. We therefore conclude, that the sign change of the pair correlation is due to residual pairing on the quantum dot in the doublet phase which decreases with $\Delta$.

### D. Spectral function

All quantities studied so far suggest that a first order phase transition occurs when we tune the system from the 0-Junction to the $\pi$-Junction regime. This can be confirmed by studying dynamical quantities such as the spectral function.

In Fig. 14, we show the spectral function $A(\omega)$ of the quantum dot as a function of $\Delta$. The data has been calculated from the CTQMC data for the Green’s function $G^{\uparrow\downarrow}_d(\tau)$ using stochastic analytic continuation\(^{36-37}\). This method works especially well for the low energy spectrum and sharp excitations while the high energy spectrum and
excitation continua are more difficult to resolve. Inside the gap, the formation of Andreev bound states can be seen very well.

In the region of $\Delta \approx 0$ we see the Kondo-resonance. As a function of growing values of $\Delta$ and as a consequence of the opening of the quasiparticle gap at the Fermi level, the Kondo resonance evolves to Andreev bound state. Note that at the mean-field level, the Kondo resonance merely corresponds to a virtual bound state. Opening a quasiparticle gap at the Fermi level drives the lifetime of the this virtual bound state to infinity. In the parameter region which corresponds to the 0-Junction regime of the Josephson current ($\Delta \approx 0 \ldots 0.1$), we observe Andreev bound states with excitation energies approaching $\omega = 0$. This corresponds to the crossing point in Fig. 14 and has also been observed by Bauer et al. for fixed $\Delta$ and increasing $U$ in[13].

The comparison of the Quantum Monte Carlo data shown in Fig. [14] with the result obtained from the effective model discussed in Sec. III D is particularly insightful. The spectral signature is very similar except for the lack of the Kondo resonance due to the finite size of the effective model. In the effective model, the Andreev bound state excitation corresponds to the energy difference between the ground states of the singlet and the doublet phase. The position $\Delta$ at which the Andreev bound states cross at $\omega = 0$ has been identified as a clear sign for the crossing of the ground states of the singlet and doublet phases. Hence, we interpret the crossing of the Andreev bound states in the CTQMC data as a very strong sign for a level crossing and hence a first order phase transition from the singlet to the doublet phase in the full model.

E. Dynamical spin structure factor

In addition to the spectral function, the dynamical spin structure factor $S(\omega)$ defined in Eq. 22 provides a way of characterizing the phases of the system. For $\Delta = 0$, we clearly see a suppressed spectral weight at $\omega = 0$ and a peak which corresponds to the characteristic energy scale of the Kondo temperature $T_K$. From the peak position, we obtain a rough estimate for the Kondo temperature of $T_K \approx 0.06$.

From $\Delta \approx 0.05$ onwards, spectral weight is accumulated at $\omega = 0$ ultimately forming a pronounced sharp local moment peak for large values of $\Delta$. As the Kondo temperature is a measure for the energy required to break the Kondo singlet, we expect the Kondo effect to break down at a value of $\Delta \approx T_K$. This is indeed observed in Fig. 15.

The signature of the breakdown of the Kondo resonance also shows up in the spectral function plotted Fig. 14. Since the Kondo resonance stems from a screening of the magnetic moment by conduction electrons in an energy window $T_K$ around the Fermi level, the opening of a single particle gap of order $T_K$ destroys the Kondo resonance giving way to an Andreev bound state.

The breakdown of the Kondo resonance is accompanied by a change of the curvature in the current-phase-relation of the Josephson current which is a precursor for the transition to the 0° phase (see the curves for $\Delta = 0.05$ and $\Delta = 0.08$ in Fig. 7). We also observe that after the transition from the $\pi$- to the $\pi$- regime has occurred (see the current-phase-relation of the Josephson current of Fig. 8) the peak at finite $\omega$ vanishes and all the spectral weight is accumulated in the very sharp local moment
peak at \( \omega = 0 \).

\[ S(\omega) \]

FIG. 15: (Color online) Dynamical spin structure factor \( S(\omega) \) as a function of \( \Delta \) for the parameters \( \beta = 100, U = 1.0 \) and \( V = 0.5 \) at half filling and zero phase difference between the two superconductors. For \( \Delta = 0 \) we can roughly estimate the Kondo-Temperature \( T_K \approx 0.06 \) from the peak position of \( S(\omega) \).

F. Charge gap

From the dynamical charge structure factor, we can determine the gap \( \Delta_c \) to local charge fluctuations on the dot with two different methods. One way to extract the charge gap is to read off the peak position of the lowest lying excitation in the dynamical charge structure factor obtained from the charge correlation function \( C_c(\tau) = \langle \hat{n}(\tau) \hat{n} \rangle - \langle \hat{n} \rangle \langle \hat{n} \rangle \) via stochastic analytic continuation. The other way of extracting the charge gap from \( C_c(\tau) \) is based on the fact, that the charge structure factor \( N(\omega) \) is linked to \( C_c(\tau) \) via

\[ C_c(\tau) \propto \int_{-\infty}^{\infty} d\omega \ e^{-\tau \omega} N(\omega). \quad (36) \]

If \( N(\omega) \) is sharply peaked around a certain value \( \omega_p \), we can approximate \( N(\omega) \) by \( N(\omega) \approx \delta(\omega - \omega_p) \). This corresponds to \( C_c(\tau) \approx e^{-\tau \omega_p} \). Therefore, a least squares fit of an exponential function \( e^{-\tau \omega_p} \) to \( C_c(\tau) \) in a region where only one single mode dominates, can reveal the frequency \( \omega_p \) at which \( N(\omega) \) is peaked. The applicability of the method can be seen in the half logarithmic plot of \( C_c(\tau) \), where a sharply peaked charge structure factor \( N(\omega) \) is reflected by a region, in which \( C_c(\tau) \) can be well approximated by a straight line.

The data obtained using these methods is shown in Fig. 16. In the context of the effective model discussed in Sec. III F, we observe, that the behavior of the charge gap of the full model clearly differs from that of the effective model. Especially, we do not see any signature of the phase transition in the behavior of the charge gap.

The charge gap opens approximately linearly with \( \Delta \). It is very hard to extract the charge gap from the numerical data at small \( \Delta \), therefore we can only extrapolate to \( \Delta = 0 \). Here, it appears, that we have a finite charge gap even in the absence of superconductivity.

The fact that the local charge fluctuations remain gaped confirms the picture that the 0 to \( \pi \) transition occurs only in the spin sector.

VI. DMFT

A. Periodic Anderson Model with BCS conduction band

In the previous sections, we have studied the first order phase transition in the impurity model \([1]\). As the dynamical mean field theory (DMFT) provides a link between impurity models and lattice models, we can ask the question if the singlet to doublet phase transition observed in the impurity model is also realized in a corresponding lattice model.
An appropriate lattice model will of course include a \( U(1) \) symmetry breaking term like the impurity model \( \text{(1)} \) does, and in fact in the framework of the DMFT, a periodic Anderson model extended by the BCS mean field Hamiltonian (BCS-PAM) for the conduction band electrons corresponds to the impurity model presented in the previous section\( ^{39} \). The Hamiltonian of the BCS-PAM is given by:

\[
H = H_c + H_f + H_V
\]

with

\[
H_c = \sum_{k,\sigma} \xi(k) c_{k,\sigma} ^\dagger c_{k,\sigma} - \Delta \sum_k \left( \tilde{c}_{k,\uparrow} ^\dagger \tilde{c}_{-k,\downarrow} ^\dagger + \text{h.c.} \right) \tag{38}
\]

\[
H_f = \sum_{k,\sigma} \xi_f \tilde{f}_{k,\sigma} ^\dagger \tilde{f}_{k,\sigma} + U \sum_{ij} \left( \tilde{n}_{i,\uparrow} - \frac{1}{2} \right) \left( \tilde{n}_{j,\downarrow} - \frac{1}{2} \right) \tag{39}
\]

\[
H_V = -V \sum_{k,\sigma} \left( \tilde{c}_{k,\uparrow} ^\dagger \tilde{f}_{k,\sigma} + \text{h.c.} \right) \tag{40}
\]

We have considered a square lattice with hopping matrix element \( t \) between the conduction electrons such that:

\[
\xi(k) = -2t \left( \cos(kx_a) + \cos(ky_b) \right). \tag{41}
\]

Note, that the impurity model \( \text{(1)} \) has a large range of applications in the DMFT ranging from the attractive Hubbard model with \( U(1) \) symmetry broken solutions studied in references\( ^{38,39} \) to the BCS-PAM, which is considered here.

The treatment of this model within DMFT involves the same steps as for the impurity model \( \text{(1)} \), introducing a particle-hole transformation for the spin down operators. The Hamiltonian can then be cast in the form \( H = H_0 + H_U \) with

\[
H_0 = \sum_k c_k ^\dagger E(k) c_k - V \sum_k \left( c_k ^\dagger \sigma \cdot f_k + \text{h.c.} \right) + \sum_k \epsilon_f f_k
\]

and

\[
H_U = -U \sum_{ij} \left( n_{i,\uparrow} - \frac{1}{2} \right) \left( n_{j,\downarrow} - \frac{1}{2} \right). \tag{42}
\]

Here, \( \Delta \) is the matrix element \( \epsilon_f \). The reference model is the BCS-PAM.

\[
H_f = \sum_{k,\sigma} \xi_f \tilde{f}_{k,\sigma} ^\dagger \tilde{f}_{k,\sigma} + U \sum_{ij} \left( \tilde{n}_{i,\uparrow} - \frac{1}{2} \right) \left( \tilde{n}_{j,\downarrow} - \frac{1}{2} \right)
\]

\[
H_V = -V \sum_{k,\sigma} \left( \tilde{c}_{k,\uparrow} ^\dagger \tilde{f}_{k,\sigma} + \text{h.c.} \right)
\]

We have used the same Nambu-spinor notation as in Sec. \( \text{(1)} \) with the exception, that \( d \) operators have been renamed \( f \) to be consistent with the literature\( ^{38,39} \).

\[\text{B. DMFT with superconducting medium}\]

The standard DMFT can be easily adapted to a superconducting bath using the Nambu formalism\( ^{38} \). We obtain the self consistency equation for a finite lattice with \( N \) sites expressed by a \( 2 \times 2 \) matrix equation:

\[
G^\text{ff}(i\omega_n) = \frac{1}{N} \sum_k \left[ G_{kk}^\text{0ff}^{-1}(i\omega_n) - \Sigma^\text{ff}(i\omega_n) \right]^{-1} \tag{43}
\]

\[\text{C. Hysteresis}\]

In the DMFT, we can calculate the double occupancy \( \langle \tilde{f}_{i,\uparrow} \tilde{f}_{i,\downarrow} \rangle \) of the \( f \) sites, which is together with the assumption of a homogeneous system proportional to \( g_\text{0} \). Therefore, we expect a jump in the double occupancy to appear at a critical value of \( U \), if we have a first order phase transition as in the impurity problem.

**Figure 17** shows our result for the double occupancy of the \( f \) sites as a function of \( U \). Depending on the initial choice of the self energy in the DMFT cycle, we obtain two different solutions. If we start with the local Green’s function of the bare lattice model, \( \Sigma^\text{ff} \), we obtain the upper branch of the hysteresis. The lower branch is obtained by taking the self energy of the solution in the strong coupling phase at \( U = 0.44 \) as starting point for the DMFT iterations.
coexistence of two solutions is a strong hint that a first order phase transition occurs.

It should be noted that beginning at a value of \( U \approx 0.34 \), the upper branch of the hysteresis becomes unstable, i.e. the inherent fluctuations of the Monte Carlo results suffice to drop from the upper branch of the hysteresis to the lower branch after a certain number of iterations. Increasing the number of Monte Carlo measurements delays the drop to the lower branch to a higher number of iterations. This behavior can be understood in the following way: In the coexistence region, the grand potential \( \Omega \) of the upper and lower branch of the hysteresis cross at a certain value of \( U \). For small values of \( U \), \( \Omega \) is minimal on the upper branch, while the lower branch is metastable, for larger values of \( U \), however, the stable solution is the lower branch.

In the strong coupling phase and on the lower branch of the hysteresis, the Monte Carlo results suddenly develop a finite magnetization corresponding to a frozen spin. This is due to divergent autocorrelation times in the Monte Carlo simulation and is linked to the physical formation of a local moment.

D. Local dynamical spin structure factor

To further classify the weak and strong coupling phases, we calculate the local dynamical spin structure factor \( S(\omega) = \frac{1}{N} \sum_{\mathbf{q}} S(\mathbf{q},\omega) \). The Lehmann representation for \( S(\omega) \) is given by Eq. (22), where in this case \( S_+ = S^f_+ \).

\[ S(\omega) \]

\[ 0 \quad 0.05 \quad 0.1 \quad 0.15 \quad 0.2 \quad 0.25 \quad 0.3 \quad 0.35 \quad 0.4 \]

\[ 0 \quad 50 \quad 100 \quad 150 \quad 200 \quad 250 \quad 300 \quad 350 \]

\( \omega \)

\( S(\omega) \) upper
\( S(\omega) \) lower

\( \Delta = 2.0, \beta = 150, V = 0.5, U = 0.34 \)

Dynamical Spin Structure

As in the impurity case, \( S(\omega) \) is a measure for the energy needed to flip the spin on an \( f \)-site. Figure 18 shows the result for the local dynamical spin structure factor on both branches of the hysteresis. The solution corresponding to the upper branch of the hysteresis is linked to the weak coupling regime and shows a characteristic energy scale required for flipping a spin.

The lower branch of the hysteresis represents the strong coupling phase and shows a clear local moment peak in the dynamical spin structure factor at \( \omega = 0 \).

This behavior reflects exactly the single impurity physics discussed in the previous section where we observed the Kondo effect in the weak coupling phase and the formation of a local moment in the strong coupling phase.

E. \( f \)-Density of states

In order to investigate the behavior of the \( f \)-bands at the phase boundary and to be able to compare with the single impurity model, we calculate the density of states for the \( f \)-sites \( \rho_\mathit{ff} \) directly from the local Green’s function \( G(\tau) \) using the stochastic analytic continuation method for different values of \( U \). From Fig. 19 one can recognize the signature of the impurity physics (see Sec. V D), namely the crossing of Andreev bound states in the vicinity of the first order transition at \( U \approx 0.35 \). Note, that we have only shown the level crossing for the impurity model if \( \Delta \) is changed, but for varying \( U \), the crossing of the Andreev bound states in the impurity model (1) has been observed by Bauer et al.\[18\]. Clearly in the lattice model, one expects the Andreev bound states to acquire a dispersion relation which shows up as a finite width in \( \rho_\mathit{ff} \).

\[ \rho_\mathit{ff}(\omega) \]

\[ 0 \quad 0.05 \quad 0.1 \quad 0.15 \quad 0.2 \quad 0.25 \quad 0.3 \quad 0.35 \quad 0.4 \]

\[ 0 \quad 0.1 \quad 0.2 \quad 0.3 \quad 0.4 \]

FIG. 19: Density of states for the \( f \)-electrons as a function of \( U \) for the parameters \( V = 0.5, \Delta = 2, \mu = \epsilon_f = 0 \) and \( \beta = 100 \).

F. Dispersion relation of Andreev bound states

We have seen in the previous subsections, that the local physics of the single impurity model can be carried over to the lattice case within the DMFT approximation. Here, we concentrate on unique features of the lattice model \[57\], namely the dispersion relation of the \( f \)-bands.
as obtained by analyzing the single particle spectral function.

Using the local self-energy of the DMFT, \( \Sigma^{\text{df}}(i\omega_n) \), this quantity is extracted from the Green functions

\[
G^{\text{ff}}_{kk}(i\omega_n) = \left[ G^{0,\text{ff}}_{kk}(i\omega_n)^{-1} - \Sigma^{\text{ff}}(i\omega_n) \right]^{-1},
\]

(44)

and

\[
G^{cc}_{kk}(i\omega_n) = G^{0,cc}_{kk}(i\omega_n) - G^{0,\text{ff}}_{kk}(i\omega_n)G^{\text{ff}}_{kk}(i\omega_n)G^{0,fe}_{kk}(i\omega_n),
\]

(45)

where \( G^{0,\text{ff}}_{kk}(i\omega_n), G^{0,cc}_{kk}(i\omega_n), G^{0,\text{ff}}_{kk}(i\omega_n) \) denote the noninteracting Green functions for the corresponding orbitals in the unit cell.

Using the stochastic analytic continuation, these Green’s functions can be rotated to real frequencies, yielding in principle the spectral function \( A(k, \omega) \). For each \( k \)-point and real frequency this quantity is a \( 4 \times 4 \) matrix since we have a \( 2 \times 2 \) Nambu spectral function for each combination of \( f \) and \( c \) orbitals. Our analysis of the spectral function is based on the basis independent quantity \( A(k, \omega) = \text{Tr} A(k, \omega) \).

![Trace of the spectral function \( A(k, \omega) \) at \( U = 0.125 \)](image)

**FIG. 20:** Trace of the spectral function \( A(k, \omega) \) at \( \beta = 100 \) in the singlet regime. The parameters of the simulation were given by \( U = 0.125, V = 0.5, \Delta = 2 \) and \( \mu = \epsilon_f = 0 \).

Fig. 20 plots this quantity in the singlet phase. The overall structure of the spectral function is similar to the structure observed for the bare BCS-PAM characterized by the four bands:

\[
E_{\pm, \pm}(k) = \pm \sqrt{V^2 + E^2(k)} \pm E(k) \sqrt{V^2 + E^2(k)} / 2
\]

(46)

where \( E(k) = \sqrt{\epsilon^2(k) + \Delta^2} \). The bands with dominant \( c \)-character, \( E_{\pm, \pm}(k) \equiv E_{\pm, c}(k) \), at high frequencies are well separated from the bands of dominant \( f \)-character at low frequencies, \( E_{\pm, f}(k) = E_{\pm, -f}(k) \). For the considered bare parameters, \( V \) is the smallest scale and sets the magnitude of the dispersion relation of the \( f \)-band. In particular expanding in \( V \) gives:

\[
E_{\pm, f}(k) = \pm \frac{V^2}{E(k)} + O \left( \frac{V^4}{E(k)^3} \right)
\]

(47)

Starting from the point of view of the impurity model, which as seen above accounts very well for overall form of the \( k \)-integrated \( f \)-spectral function, \( E_{\pm, f}(k) \) may be perceived as the dispersion relation of the Andreev bound states.

![Trace of the spectral function \( A(k, \omega) \) at \( U = 0.125 \)](image)

![Trace of the spectral function \( A(k, \omega) \) at \( U = 0.25 \)](image)

**FIG. 21:** Trace of the spectral function \( A(k, \omega) \) at \( \beta = 100 \) in the singlet regime for increasing interaction \( U \). The width of the \( f \)-bands clearly decreases and the dispersion becomes weaker. The parameters of the simulations were given by \( V = 0.5, \Delta = 2 \) and \( \mu = \epsilon_f = 0 \).

The singlet phase is continuously connected to the \( U = 0 \) point. Starting from this limit, we can account
for the Hubbard $U$ within a slave boson approximation\textsuperscript{12} which will renormalize the hybridization matrix element to lower values. Owing to Eq. 47 this suppresses the dispersion relation of the $f$-electrons. This aspect is clearly observed in Fig. 21.

\begin{equation}
S_{MF} = \int_0^\beta d\tau \int_0^\beta d\tau' \tilde{G}^{-1}(\tau-\tau') \tilde{f}(\tau') - \frac{U m_z}{2} \int_0^\beta d\tau \tilde{f}(\tau) \tilde{f}(\tau)
\end{equation}

where $\tilde{f}^\dagger = (\tilde{f}^\dagger_1, \tilde{f}^\dagger_\downarrow)$ and $\tilde{G}(\tau-\tau')$ corresponds to the bath Green function. To account for disorder, the $z$-component of the $f$-spin is sampled from the box distribution $m_z \in [-M_z, M_z]$. Averaging over disorder at each iteration in the DMFT cycle yields the spectral function shown in Fig. 23. As apparent, the disorder average generates a finite lifetime.

FIG. 23: Trace of the spectral function $A(k,\omega)$ as obtained from using Eq. [49] for the impurity action. The $z$-component of the local moment is sampled from the box distribution $m_z \in [-M_z, M_z]$. The parameters used for this plot were given by $V = 0.5$, $U = 0.5$, $\Delta = 2$ and $M_z = 0.0375$. Here, the calculations are carried out on the real time axis such that no analytical continuation is required.

In the doublet phase, $U > U_c$, the paramagnetic slave-boson mean-field approach fails. In this state, the $f$-spin is frozen and in the DMFT cycle we have imposed spin symmetric baths thereby inhibiting magnetic ordering. The QMC data of Fig. 22 points to a very incoherent $f$-spectral function. It is therefore tempting to model this state in terms of spin disorder: the spin of the $f$-electrons on each site is static and points in a random direction. To provide some support for this picture we stay in the dynamical mean field framework but consider a mean-field decomposition of the Hubbard term in the action of the impurity problem:

\begin{equation}
U \left( \tilde{n}_{f,\uparrow} - \frac{1}{2} \right) \left( \tilde{n}_{\downarrow} - \frac{1}{2} \right) \rightarrow -\frac{U m_z}{2} (\tilde{n}_{f,\uparrow} - \tilde{n}_{f,\downarrow})
\end{equation}

This mean field approximation, accounts for the local moment formation with $z$-component of spin $m_z$. The corresponding mean-field action of the impurity model now reads:

VII. CONCLUSION

We have shown that the weak-coupling CTQMC algorithm is an extremely powerful unbiased tool to compute thermodynamic as well as dynamical quantities of impurity models in superconducting environments. The method can cope very well with a complex phase of the superconducting order parameter thereby allowing for the calculation of the Josephson current. Our detailed results for the impurity problem confirm the picture of a first order phase transition between a single and doublet state. It is accompanied by a $\pi$ phase shift in the Josephson current. Being completely unbiased, our approach provides the first numerically exact results for this model Hamiltonian.

Within DMFT, the physics of the BCS-PAM is mapped onto the single impurity Anderson model supplemented by a self-consistency loop. We have shown that within this approximation, the physics of the impurity model can be carried over to the lattice. In particular...
at fixed superconducting order parameter $\Delta$ the first order transition between a singlet and local moment state as a function of growing values of $U$ shows up in a hysteresis behavior of the double occupancy. Furthermore, the low energy features of the local $f$-spectral function are reminiscent of the Andreev bound states with vanishing excitation energy (i.e. a crossing point) at the critical coupling. Within the DMFT approximation, we can look into the single particle spectral function. In the singlet phase, the low energy features can be interpreted in terms of a dispersion relation of Andreev bound states. This state is continuously linked to the $U = 0$ limit. In the doublet state or local moment regime, the low energy features of the spectral functions are incoherent. We propose to understand this in terms of models of disorder. In particular in this state, the spin dynamics of the $f$-electron is frozen and since we are considering paramagnetic states it points in a random different direction in each unit cell. A simple model of disorder following this picture accounts very well for the observed incoherent spectral function.

VIII. ACKNOWLEDGMENTS

We thank Julia Wernsdorfer for interesting discussions and for bringing up the subject in her diploma thesis. We also wish to thank Volker Meden for fruitful discussion and advice. Part of the calculations were carried out at the Leibniz Rechenzentrum in Munich on HLRB2. We thank this institution for allocation of CPU time.

DJL also thanks Jutta Ortloff and Manuel Schmidt for many valuable discussions as well as Burkhard Ritter for critical reading of the manuscript. FFA would like to thank the KITP, where part of this work was carried out, for hospitality (NFS Grant PHY05-51164). We thank the DFG for financial support.

APPENDIX A: PROOF OF THE DETERMINANT IDENTITY

In this section a general determinant identity is proven, which can be used to derive Wick’s theorem for contributions of a configuration $C_n$ to physical observables. Let us define the vectors $u_i, v_i \in \mathbb{C}^m$ and the numbers $\alpha_{ij} \in \mathbb{C}$. Further, let $A \in \mathbb{C}^{m \times m}$ be a matrix of rank $m$. We define the non-singular matrices $M_n \in \mathbb{C}^{(m+n) \times (m+n)}$ and $A_{ij} \in \mathbb{C}^{(m+1) \times (m+1)}$ by:

$$M_n = \begin{pmatrix} A & u_1 & \ldots & u_n \\ v_1^T & \alpha_{11} & \ldots & \alpha_{1n} \\ \vdots & \vdots & \ddots & \vdots \\ v_n^T & \alpha_{n1} & \ldots & \alpha_{nn} \end{pmatrix}, \quad A_{ij} = \begin{pmatrix} A & u_{ij} \\ v_i^T & \alpha_{ij} \end{pmatrix}. \quad (A1)$$

With these definitions, the following determinant identity holds:

$$\det M_n(\det A)^{n-1} = \det \begin{pmatrix} \det A_{11} & \ldots & \det A_{1n} \\ \vdots & \ddots & \vdots \\ \det A_{n1} & \ldots & \det A_{nn} \end{pmatrix}. \quad (A2)$$

The identity can be proven by induction in $n$. It is trivial for $n = 1$, so we have to start with $n = 2$, where we have to show

$$\frac{\det M_2}{\det A} = \frac{\det A_{11}}{\det A} \frac{\det A_{22}}{\det A} - \frac{\det A_{12}}{\det A} \frac{\det A_{21}}{\det A}. \quad (A3)$$

For the following calculations, we introduce several vectors:

$$u_{ij}^1 = \begin{pmatrix} u_j \\ \alpha_{ij} - 1 \end{pmatrix}, \quad v_{ij}^2 = \begin{pmatrix} v_i \\ 0 \end{pmatrix}, \quad u_2^2 = v_1^1 = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \in \mathbb{C}^{m+1}.$$ \quad (A4)

$$u_M^1 = \begin{pmatrix} u_2 \\ \alpha_{12} \\ \alpha_{22} - 1 \end{pmatrix}, \quad v_M^2 = \begin{pmatrix} v_2 \\ \alpha_{21} \\ 0 \end{pmatrix}, \quad u_M^2 = v_M^1 = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \in \mathbb{C}^{m+2}. \quad (A5)$$

Let us define the expanded matrix $C_{ex}$ of a square matrix $C$ as the matrix $C$ expanded by one row and one column containing a unit vector:

$$C_{ex} = \begin{pmatrix} C & 0 \\ 0^T & 1 \end{pmatrix}. \quad (A6)$$

As a last definition, we introduce the abbreviation $b_{ij} = v_i^T A^{-1} u_j$. Using these notations, we can write the matrices $A_{ij}$ as

$$A_{ij} = A_{ex} + u_{ij}^1 v_{ij}^{1T} + u_2^2 v_{ij}^{2T}. \quad (A7)$$

To calculate the determinant $\det A_{ij}$, we use the matrix determinant lemma $\det(A + uv^T) = (1 + v^T A^{-1} u) \det A$, yielding

$$\frac{\det A_{ij}}{\det A_{ex}} = \left[ 1 + v_{ij}^T (A_{ex} + u_{ij}^1 v_{ij}^{1T})^{-1} u_2^2 \right] \left( 1 + v_{ij}^T A_{ex}^{-1} u_{ij}^1 \right). \quad (A8)$$

The inverse matrix of $(A_{ex} + u_{ij}^1 v_{ij}^{1T})$ can be obtained from the Sherman-Morrison formula and a tedious calculation making use of the special form of the vectors and matrices gives the result

$$\det \frac{A_{ij}}{A_{ex}} = \alpha_{ij} - b_{ij}. \quad (A9)$$

From this, the right hand side of Eq. (A3) can be easily obtained. For the left hand side, we have to perform an analogous calculation using the decomposition of the matrix $M_2$:

$$M_2 = A_{11ex} + u_M^1 v_M^{1T} + u_M^2 v_M^{2T}. \quad (A10)$$
Again, we apply the matrix determinant lemma two times and insert the Sherman-Morrison formula to calculate the inverse matrix of \((A_{11} + u_M v_M^T)\). Simplifying the result as far as possible, we finally arrive at

\[
\frac{\det M_2}{\det A} = (\alpha_{11} - b_{11}) (\alpha_{22} - b_{22}) - (\alpha_{12} - b_{12}) (\alpha_{21} - b_{21}).
\]  

If we compare (A11) with (A9), it is clear, that Eq. (A3) holds.

We now assume that for a certain value \(n \in \mathbb{N}\), Eq. (A2) holds. For \(n + 1\), we can cast the matrix \(M_{n+1}\) in a form, where we can make use of Eq. (A2) holding for \(n\):

\[
M_{n+1} = \begin{pmatrix}
\tilde{A} & \tilde{u}_2 & \ldots & \tilde{u}_{n+1} \\
\tilde{v}_2^T & \alpha_{2,2} & \ldots & \alpha_{2,n+1} \\
\vdots & \vdots & \ddots & \vdots \\
\tilde{v}_{n+1}^T & \alpha_{n,2} & \ldots & \alpha_{n,n+1}
\end{pmatrix},
\]

where we have introduced the new matrix \(\tilde{A}\) and the vectors \(\tilde{u}_i\) and \(\tilde{v}_i\) with:

\[
\tilde{A} = \begin{pmatrix} A \\ v_1^T \end{pmatrix} \begin{pmatrix} u_1 \\ \alpha_{11} \end{pmatrix}, \quad \tilde{u}_i = \begin{pmatrix} u_i \\ \alpha_{1i} \end{pmatrix}, \quad \tilde{v}_i = \begin{pmatrix} v_i \\ \alpha_{i1} \end{pmatrix}.
\]

Further, we need the matrices \(\tilde{A}_{ij}\) defined analogously to (A1):

\[
\tilde{A}_{ij} = \begin{pmatrix} A \\ v_1^T \end{pmatrix} \begin{pmatrix} u_1 \\ \alpha_{1i} \end{pmatrix} = \begin{pmatrix} A \\ v_1^T \end{pmatrix} \begin{pmatrix} u_j \\ \alpha_{ij} \end{pmatrix}
\]

With these definitions, and with the abbreviations \(a_{ij} = \det A_{ij}\) and \(\tilde{a}_{ij} = \det \tilde{A}_{ij}\), we are now able to apply Eq. (A2) holding for \(n\):

\[
\det M_{n+1} (\det \tilde{A})^{(n-1)} = \det \begin{pmatrix} \tilde{a}_{2,2} & \ldots & \tilde{a}_{2,n+1} \\
\vdots & \ddots & \vdots \\
\tilde{a}_{n+1,2} & \ldots & \tilde{a}_{n+1,n+1}
\end{pmatrix}.
\]  

For \(\tilde{a}_{ij}\), we make use of Eq. (A2) with \(n = 2\), which we have proved above:

\[
\tilde{a}_{ij} = \frac{1}{\det A} (a_{11}a_{ij} - a_{1i}a_{1j}).
\]

Inserting this result in (A15) yields a determinant with entries of the form \(a_{11}a_{ij} - a_{1i}a_{1j}\). We make use of the multi-linearity of the determinant to decompose this expression and we obtain a sum of determinants with factors of the form \(a_{ij}\). Eliminating zero contributions, the resulting expression corresponds precisely to the Laplace-expansion of a larger determinant, and we finally obtain

\[
\det M_{n+1} \det A^n = \det \begin{pmatrix} a_{1,1} & a_{1,2} & \ldots & a_{1,n+1} \\
a_{2,1} & a_{2,2} & \ldots & a_{2,n+1} \\
\vdots & \vdots & \ddots & \vdots \\
a_{n+1,1} & a_{n+1,2} & \ldots & a_{n+1,n+1}
\end{pmatrix}.
\]  

This is the identity (A2) for \(n + 1\). Hence we have derived the determinant identity for \(n + 1\) using only the identity for \(n\) and \(n = 2\). By induction, the identity (A2) therefore holds for every \(n \in \mathbb{N}\), as it is trivial for \(n = 1\).

correlation function \( C_c(\tau) = \langle \tilde{n}(\tau)\tilde{n} \rangle - \langle \tilde{n} \rangle \langle \tilde{n} \rangle \) using stochastic analytic continuation. This, however is numerically demanding and requires a very high quality of data. In the present case, we were unable to extract more than the lowest lying excitation of the dynamical charge structure factor, which is directly connected to the charge gap. The higher energy spectrum showed an extremely complex structure which is difficult to capture with stochastic analytic continuation.

42 Strictly speaking, the reference model in the DMFT only has one superconducting bath, while we introduced a left and a right bath in the Hamiltonian [1]. However, in the CTQMC, the reference model is entirely encoded in the bare Green's function, which can be understood as an action representation in the path integral formalism. The explicit number of the superconducting baths is therefore unimportant.
