Abstract. Greening waste presents considerable reuse potential owing to its simple organic composition. For greening waste, being simply regarded as ordinary garbage cannot adapt to the requirements of sustainable and harmless development. Resource reusing process is an inevitable trend. Utilization of urban landscape greening waste is of great significance for improving the ecological environment in urban and rural areas, building a harmonious city, increasing employment, and enhancing economic efficiency. This will be a far-reaching impact on China's economic and social sustainable development. In this work, eight typical landscape plants were selected as raw materials using the batch reactor. The concept of stepwise hydrothermal conversion and a real model with xylose, cellulose acetate (CA), and aromatic aldehyde as the target products were thereby constructed. In the third step of the stepwise conversion, the effect of reaction temperature and time in the oxidative degradation of cellulose acetate solid residues in NaOH solution to produce aromatic aldehyde was investigated. The optimum conditions were obtained as 175 ℃ and 90 min. The yield of aromatic aldehydes in all 16 branches and leaves of cellulose acetate all reached about 20% under the optimal conditions.

1 Background

1.1 Preparation of aromatic aldehydes by wet oxidative degradation of lignin

Wet oxidation refers to the process in which organic or inorganic substances in aqueous solution or suspension are oxidized by oxidants at higher temperature and pressure [1,2]. The operating temperature and pressure range are 100 ℃ ~ 320 ℃ and 0.5MPa ~ 20MPa [3]. Although some studies on wet oxidation of lignin have been applied to wastewater treatment, others have focused on the production of organic acids through lignin oxidation [4,5]. However, most of the wet oxidative degradation of lignin is used to produce aromatic aldehydes, such as vanillin (VLA), syringaldehyde (SA) and p-hydroxybenzaldehyde (PHBA) [4-6]. These compounds have many applications, especially vanillin is widely used in food, cosmetics, and pharmaceutical industries as condiments and spices. However, among these products, only vanillin has been industrialized.

1.2 Catalysis

Catalysts are usually used in wet oxidation of lignin to improve the yield of aromatic aldehydes. These catalysts mainly include noble metals, transition metal salts and perovskite compounds [7,8]. Precious metals have a great catalytic effect. For example, compared with the oxidation process without catalyst, palladium catalyst can increase the yield of aromatic aldehydes by 10-20 times [9]. In addition, precious metals usually exist as solid particles, which is conducive to recovery and reuse. However, due to the high cost of precious metals, the economy of commercial application is poor. Compared with precious metals, transition metal salts have lower cost and more potential for industrial application. Transition metal salts are usually water-soluble, so they are always used as homogeneous catalysts, and their isomerization can produce higher catalytic activity. Cu²⁺ is considered to be the most effective homogeneous catalyst [10]. One of the problems affecting the industrial application of homogeneous catalysts is that it is difficult to recover them. For example, about 40% of the homogeneous catalyst phosphomolybdic acid is lost as the reaction medium when reaching the final process. In addition, these homogeneous transition metal salts can lead to the secondary pollution of the discharged water to the environment. Deng et al. [11-16] has made great contributions to the research of perovskite oxide catalysts. They have found that these perovskite oxide catalysts exhibit high activity and stability in the wet oxidation of lignin. However, compared with transition metal catalysts, these perovskite oxides require additional sol-gel process.

1.3 Effect of reaction conditions

The degradation of lignin to aromatic aldehydes is a complex reaction. Syringaldehyde, vanillin and \( p \)-hydroxybenzaldehyde are intermediates of lignin wet oxidation process, which are derived from three basic structural units of lignin. These aldehydes can be formed under appropriate conditions because the activation energies of these aldehydes are much higher than those of lignin. The initial degradation reaction of lignin is faster because of its lower activation energy (4426kJ/mol) [10]. 100-190 °C is the commonly used suitable temperature range. In addition, the molecular weight of lignin has a great influence on the preparation of vanillin [17,18], and lignin with low molecular weight usually has higher vanillin yield.

2 Experimental

2.1 Pretreatment of greening waste

The discarded pine branches were collected from Handan Road Campus of Fudan University in Shanghai, China. After the raw branches and leaves were just trimmed by the workers are collected, they are dried in an oven at 105 °C for 8 hours, and then mechanically crushed through a 40 mesh sieve, and the screened samples are kept for standby.

2.2 Catalytic oxidation of cellulose acetate solid residue

The lignin conversion rate was calculated according to the lignin mass (m) in the original cellulose acetate solid residue. The mass weight of aromatic aldehydes in the extracted liquid was determined by GC-MS external standard method (e.g., Fig. 1, 2, 3 and 4), and the yield of aromatic aldehyde was finally calculated based on the weight of cellulose acetate residues.

3 Results and Discussion

3.1 Effect of reaction temperature

Table 1 shows the effects of other conditions and different reaction temperatures on the oxidative degradation of cellulose acetate to aromatic aldehydes.

| Temperature (°C) | VLA (g) | SA (g) | PHBA (g) | Lignin Conversion rate (%) | Total Yield (%) |
|------------------|---------|-------|----------|---------------------------|-----------------|
|                  |         |       |          |                           |                 |
According to the data in the table above, the conversion and yield of lignin are relatively low at lower temperature. When the temperature was too high, the conversion of lignin reached 100%, but the yield was lower than that at 175 °C. This indicates that temperature can significantly affect the wet oxidation reaction of cellulose acetate solid residues, and proper temperature can make the conversion of lignin and the yield of aromatic aldehydes reach the maximum.

3.2 Effect of reaction time

Table 2 shows the effect of reaction time on the preparation of aromatic acids by oxidative degradation of cellulose acetate. It can be seen from the table that when the reaction temperature is 90 min, the conversion of lignin and the yield of aromatic aldehydes reach the maximum value. If the reaction time is too long, the side reaction will be increased and the yield of aromatic aldehyde will be reduced [17].

Table 2. Effect of reaction time on catalytic oxidation of cellulose acetate solid residue (Pine branch).

| Time (min) | VLA (g) | SA (g) | PHBA (g) | Lignin Conversion rate (%) | Total Yield (%) |
|------------|---------|--------|----------|---------------------------|-----------------|
| 30         | 0.023   | 0.013  | 0.008    | 67.3                      | 8.8             |
| 60         | 0.034   | 0.018  | 0.010    | 86.5                      | 12.4            |
| 90         | 0.065   | 0.032  | 0.022    | 100                       | 23.8            |
| 120        | 0.043   | 0.021  | 0.015    | 100                       | 15.8            |

3.3 Yield of residual aromatic aldehydes from cellulose acetate of other greening wastes

The acetylation of other greening wastes activated by phosphoric acid (conditions: temperature 150 °C, time 1.8 h, liquid-solid ratio 8 ml/g, phosphoric acid concentration 1.67%) was carried out (conditions: acetic acid/acetic anhydride = 18 ml/18 ml, 3 g solid residue, 60 °C, 4 h, 300 rpm), and then the obtained solid residues were subjected to the optimized catalytic oxidation conditions (cellulose acetate solid residue 3.0 g). The results are listed in Table 3.

Table 3. Yields of aromatic aldehydes from cellulose acetate solid residues of typical landscaping waste (wt%).

| Catalyst            | Branches | Leaves |
|---------------------|----------|--------|
| Pine needle         | 23.8     | 25.3   |
| Cupressus funebris  | 21.8     | 24.0   |
| Platanus            | 21.1     | 23.7   |
| Cinnamomum camphora| 19.5     | 21.8   |
| Pittosporum tobira  | 23.2     | 24.4   |

As shown in Table 3, the yield of aromatic aldehydes in all eight branches and leaves reached about 20%, and the yield of aromatic aldehydes in leaves was higher than that in branches. The average contents of cellulose, hemicellulose and lignin in leaves are lower than those in branches, which is consistent with the plant biological differences between branches and leaves. Cellulose, hemicellulose and lignin exist in the cell wall of plants, and their contents vary with different parts of the plant [19]. Cellulose is dispersed in the plant cell wall in the form of microcrystalline filaments. Hemicellulose and lignin play a filling role, and act as a skeleton to connect the crystalline filaments [7,20]. Because the cell walls of branches are more lignified, the branches usually contain more and stronger lignin and tighter lignin skeletons than leaves. Therefore, this may be the reason why the yield of aromatic aldehydes in branches is lower than that in leaves.

4 Conclusions

The oxidation degradation of cellulose acetate in NaOH solution to produce aromatic aldehydes was investigated by single factor test. The optimum reaction temperature was 175 °C and the reaction time was 90 min. Under the optimal conditions, the yield of aromatic aldehydes in all eight branches and leaves was about 20%. In addition, the yield of aromatic aldehydes in leaves was higher than that in branches.
