Abstract

Simultaneous saccharification of corn starch and fermentation to gluconic acid (SSF) was examined with *Aspergillus niger* immobilized on nonwoven fabric under high dissolved oxygen (DO). The starch liquefaction step to maltodextrins by the action of thermostable α-amylase was optimized using the dextrose equivalent value as an index. SSF was carried out using liquefied starch with simultaneous addition of commercial amylglucosidase, and *A. niger* for gluconic acid production at DO of 150 mg/l by supplying pressurized oxygen gas. Treatment with α-amylase at 86°C, followed by amylglucosidase at 30°C resulted in nearly 100% saccharification when using 300 g/l corn starch. Under conditions optimized for the saccharification steps, successful repeated batch production of gluconic acid of 272 g/l with space–time yield of 6.1 g/l/h was achieved with higher than 90% production yield from corn starch without significant loss of production activity for 450 h.

Keywords: Simultaneous saccharification; *Aspergillus niger*; Starch; Gluconic acid; Immobilization

Introduction

Gluconic acid (GA) and its salts are widely used in the food, pharmaceutical and chemical industries, and it has been identified as one of the top 30 building block compounds that can be produced from biomass in future bio refineries [1]. There have been various approaches for GA production by chemical, electrochemical, bioelectrochemical, and photo catalytic approaches [2-4]. Because of some limitations regarding these approaches, microbial processes have been regarded as efficient and dominant techniques for manufacturing GA [5]. To improve its production process, enzymatic biocatalysts in an enzyme bioreactor and microbial production using free-growing or immobilized cells of either Gluconobacter oxydans or *Aspergillus niger* have been used. Glucose oxidase involved in GA fermentation uses oxygen to convert glucose to GA and, therefore, its overall productivity is strongly dependent on dissolved oxygen (DO) [6]. To increase the oxygen transfer rate in submerged cultures, using oxygen-enriched gas or pressurization of the reactor vessel is an alternative to increasing the stirring speed, air flow rate and so on. Sakurai et al. [7] reported that maximum productivity was obtained at DO up to 150 mg/l, which could be attained only with pressurized oxygen gas supplementation. Immobilization of whole cells or glucose oxidase enzyme by various techniques has also been reported to be a useful approach for the production of GA. Nonwoven fabric has been used as a support for immobilizing proteins [8] or whole cells [9] since it is porous, has a large surface area, and can be easily processed. In addition, it is feasible to use cheap raw materials such as cellulose, molasses, starch and whey for the fermentation, and simultaneous saccharification of such materials for the fermentation (SSF) has been used in an efficient process with ethanol [10,11], lactic acid [12,13], etc. Since SSF for GA production from starch is considered to be comprised of starch solubilization by heating, followed by the liquefaction/saccharification of starch and GA production, thermostable or thermophilic amylase aided liquefaction might be useful to avoid the gelatinization of the solubilized starch.

In this study, production of GA from starch in a oxygen pressurized reactor was optimized for efficient repeated production with *Aspergillus niger* immobilized on nonwoven fabric with the use of thermostable amyrase from Bacillus sp. for liquefaction of starch.

Materials and Methods

Chemicals

Amyloglucosidase (AMG) from *Rhizopus* sp. (11,600 units/g-protein), and α-amylase (AAM) from *Bacillus subtilis* (20,000 units/g-protein), and α-amylase (AAM) from *Bacillus subtilis* were purchased from Sigma-Aldrich Inc. (St Louis, MO), and Wako Pure Chemical Industries Ltd., Osaka, Japan, respectively. Nonwoven fabric, made of a rayon and polyacrylonitrile mixture (RA), was prepared and kindly supplied by Japan Vilene Co. Ltd. (Tokyo, Japan). All other materials were of the highest purity commercially available and were used without further purification.

Microorganism and media

*Aspergillus niger* IAM5349 (formerly IAM2094) was used throughout this study. Medium compositions used for stock culture (namely medium A), sporulation (medium B), and mycelial growth (medium C) are shown in Table 1.

Sequential hydrolysis of cornstarch by α-amylase and amyloglucosidase: Enzymes concentrations used for sequential hydrolysis of corn starch were optimized by analyzing in terms of the dextrose equivalent (DE) for the liquefaction step using α-amylase, and glucose produced in the saccharification step using amyloglucosidase. DE value was calculated by the following equation [14]:

\[
\text{DE} = \frac{\text{Glucose produced}}{\text{Starch concentration}} 
\]

Starch liquefaction was carried out by adding various concentrations of AAM to a solution composed of 300 g corn starch, 0.15 g MgSO$_4$·7H$_2$O, 0.2 g KH$_2$PO$_4$, 0.4 g Na$_2$HPO$_4$, and 0.5 g CaCl$_2$·2H$_2$O in 1,000 ml deionized water, pH 6.0, at 86°C, with a magnetic stirrer. The saccharification test using AMG was carried out at 30°C using the liquefied solution prepared as described above.

**SSF of corn starch in GA production:** GA production from liquefied starch with immobilized *A. niger* was performed in a pressure-proof column reactor as described previously [7]. Mycelia immobilized on 9.5 cm×8 cm and 18.5 cm×9.5 cm nonwoven fabric wound onto stainless steel cylindrical wire, prepared as described above, placed in the column reactor with 600 ml liquefied starch solution prepared as described above, was incubated at 30°C, under pressurization at 7 MPa and supplied with sterile oxygen gas through sintered glass filters. DO in the reactor was monitored using a DO probe (galvanic oxygen electrode Type DY-1; B. E. Marubishi Co. Ltd., Tokyo, Japan) to maintain DO at 150 mg/l.

**Analysis:** Glucose, oligosaccharide, and gluconic acid were analyzed using HPLC (L-6000; Hitachi, Ltd., Japan). For glucose and oligosaccharide analysis, a refractive index (RI) detector (Shodex RI SE-51; Showa Denko Co. Ltd., Tokyo, Japan) with a column packed with Aminex HPX-42C (Bio-Rad Laboratories Inc., Richmond, CA) was employed with deionized water as an eluent. For gluconic acid analysis, a UV detector (210 nm) with a column MCI GEL 08S (Mitsubishi Chemical Co., Tokyo, Japan) was employed with a mobile phosphate phase. The dry weight of immobilized cells was determined by subtraction of the average predetermined dry weight of nonwoven fabrics from the weight of nonwoven fabrics plus mycelium after drying at 80°C to a constant weight. Reducing sugar was determined by a modified Somogyi method [15]. The mutarotase-GOD method was also used for monitoring glucose in the pressurized bioreactor using the Glucose-C-test (Wako Pure Chemical Industries Ltd.) according to the manufacturer’s instructions.

**Results and Discussion**

**Optimization of starch saccharification with α-amylase and amyloglucosidase**

Enzymatic hydrolysis of starch to glucose involves the liquefaction of gelatinized starch with acid or thermostable α-amylase followed by saccharification to glucose by amyloglucosidase [16]. For the liquefaction step using AAM, the effect of AAM concentration on the DE value was examined as shown in Figure 1. With an AAM concentration higher than 0.01%, DE rapidly increased within 30 min to a nearly saturated level of 20, although 0.003% AAM reached less than 1 DE after 50 min. With 0.005% AAM, 10 DE could be obtained after 30 min. Gupta et al. [17] optimized the natural starch hydrolysis conditions with a liquefaction step to obtain 10 DE using AAM, followed by a saccharification step to DE 96 using AMG. In our case, 0.005% AAM treated for 30 min was concluded to be optimal for the liquefaction step.

Saccharification of liquefied corn starch with AMG was examined as shown in Figure 2. With AMG >0.4%, >100 g/l glucose was obtained.
in 1 h reaching nearly 300 g/l in 6 h, although the saccharification rate slightly decreased with 0.3% AMG. HPLC analysis of the byproducts formed after the reaction showed maltose (4.36 g/l) and maltotriose (1.05 g/l), suggesting that higher than 98% of the liquefied corn starch was saccharified under this condition. Therefore, 0.4% AMG was concluded to be suitable for saccharification in GA production to avoid the limitation of glucose feeding. Table 2 shows the results obtained with various starches under the conditions determined as above. All the starches tested except for soluble starch generated nearly 100% glucose.

Repeated batch production of gluconic acid from starch

GA production was further examined using the liquefied solution of starch with immobilized A. niger. Immobilization of mycelia was carried out as described previously [7]. Briefly, nonwoven fabric wound around stainless steel cylindrical wire was soaked in medium C containing 4x106 to 8x106 spores per ml for a few minutes, followed by aseptic incubation in oxygen gas at 30ºC for 45 h. As shown in Figure 3, the mycelia grew well not only on the surface but also penetrated the nonwoven fabric and interwined with the fiber. Dense growing of the mycelia mainly near the surface of the fabric could be due that the strain was aerobic growing fungus. For efficient production of gluconic acid, the bioreactor was used at DO of 150-200 mg/l by supplying oxygen gas that the direct using of the liquefied solution for GA production was a mean value of 0.33 g/l. Recent reports of GA production from unconventional carbohydrate sources are summarized in Table 3. Addition to the high production yield by the substrate and successful accumulation of GA at significantly higher concentration than in other studies suggest that our SSF system could be feasible for industrial applications. The space–time yield in this study corresponds to nearly three-fold that in a previous report [18], which could be due to the reaction being performed at high DO, which could be achieved only by using an oxygen gas-supplied pressurized reactor. The specific GA production rate in this study was 6.91 g-GA/g-mycelia/h. A previous study of the same strain of free cells, using glucose as the substrate was reported to be 19.6 g-glucurate/g-mycelia/h [19], approximately 3-fold that of this study; however, our system seems to have more feasible operability for continuous or repeated-batch production.

Conclusions

This paper shows that the microbial GA production from corn starch using Aspergillus niger. Optimization of the liquefaction of the starch by thermostable AAM, followed by the saccharification by AMG generated glucose with nearly 100% yield in 6 h, which could supply enough amount of glucose for GA production. Present data suggest that the direct using of the liquefied solution for GA production containing AMG was successful in case of our system. Combination of the saccharification and GA production under high DO using A. niger immobilized on nonwoven fabrics resulted in the efficient GA production (6.1 g-GA/l/h). In addition, our immobilizing system resulted in the stable repeated batch production at such level. Our system might also have an advantage in the operation of the bioreactor preventing contamination because of the high DO [22].

Table 2: Sequential saccharification of various starches with AAM and AMG.

| Starch               | D.E. (-)* | Glucose (g/l) |
|----------------------|-----------|---------------|
| Corn starch          | 10        | 294.3         |
| Potato starch        | 12        | 298.8         |
| Sweet potato starch  | 9.6       | 298.8         |
| Soluble starch       | 11.6      | 228.2         |

All reactions were carried out with 300 g/l starch under conditions as optimized for corn starch
