We analytically investigate backreaction by a quantum scalar field on two rotating Bañados-\textit{Teitelboim-Zanelli} (BTZ) geometries: that of a black hole and that of a naked singularity. In the former case, we explore the quantum effects on various regions of relevance for a rotating black hole space-time. We find that the quantum effects lead to a growth of both the event horizon and the radius of the ergosphere, and to a reduction of the angular velocity, compared to the unperturbed values. Furthermore, they give rise to the formation of a curvature singularity at the Cauchy horizon and show no evidence of the appearance of a superradiant instability. In the case of a naked singularity, we find that quantum effects lead to the formation of a horizon that shields it, thus supporting evidence for the rôle of quantum mechanics as a cosmic censor in nature.

\textbf{Introduction.} It is expected that most black holes possess some rotation (e.g., \cite{1, 2}). The geometrical structure of rotating black hole space-times is a lot richer than that of nonrotating black hole space-times. For example, in Kerr space-time [i.e., a (3 + 1)-dimensional, rotating and asymptotically flat black hole] there exists a region – the ergosphere – “near” the event horizon where observers cannot remain static: they must rotate in the same direction as the black hole. There also exists a region separated from the event horizon where an observer corotating with the horizon must have a velocity greater than or equal to the speed of light; the boundary of such a region is called the speed-of-light surface. Inside a Kerr black hole, there is also the so-called inner horizon, which is a Cauchy horizon for data “outside” the black hole. Beyond the inner horizon in the inward direction there exist closed null and timelike geodesics. None of these regions (ergosphere, speed-of-light surface or inner horizon) exist in the nonrotating limit of the Kerr geometry, a Schwarzschild black hole space-time (although an inner horizon does exist for a charged spherically-symmetric – Reissner-Nordström – black hole).

The presence of the above regions has important consequences for the physics of black holes, notably for their stability properties. For example, the inner horizon of the Reissner-Nordström solution is classically unstable \cite{3, 4} (phenomenon of “mass inflation”). A similar feature occurs in the Kerr geometry, where perturbations falling into the black hole are expected to produce a divergent curvature at the inner horizon \cite{5, 6}. The presence of the ergosphere in Kerr, in its turn, leads to the Penrose process \cite{7}, with its “collisional” variant \cite{8}, and to the phenomenon of superradiance \cite{9, 10}, whereby matter –particles in the first case and boson field waves in the second– falling into the black hole may be used in order to extract rotational energy from a black hole.

The speed-of-light surface also plays an important rôle in the existence of superradiant modes. Superradiance in general is the cause behind various classical instabilities of black holes: under massive linear field perturbations \cite{11}; when the black hole is surrounded by a mirror \cite{12} (the so-called “black hole bomb”) which encloses any part of the region outside the speed-of-light surface \cite{13}, and when a black hole lies in an anti de Sitter (AdS) universe (i.e., a universe with a negative cosmological constant) and is sufficiently small so that there exists a speed-of-light surface \cite{14, 15}. Quantum-mechanically, the existence of a speed-of-light surface seems \cite{16, 17} to be the reason why one cannot define a state describing a rotating black hole in thermal equilibrium with its own quantum boson field radiation \cite{18, 19}. One may define such quantum state, however, if one excludes the region of the space-time beyond the speed-of-light surface by placing a mirror \cite{14} or, possibly, and more naturally, by placing the rotating black hole in an AdS universe for a sufficiently large cosmological constant \cite{16}. We finally
note that the ergosphere can be present in a rotating space-time without an event horizon (such as that of a star), in which case it leads to classical instabilities of the space-time. It is of great interest to understand the fate of the stability properties and rotating space-time regions in the presence of quantum corrections. One possibility is to study the backreaction effects from quantum matter on these geometrical regions of a rotating space-time. While such a study would be technically very difficult in a Kerr black hole space-time (whether or not placed inside a mirror or a AdS universe), in this Letter we undertake that study for a rotating black hole in (2+1)-dimensions, the so-called rotating BTZ (Bañados-Teitelboim-Zanelli) black hole. This black hole possesses inner (Cauchy) and outer (event) horizons and an ergosphere but no speed-of-light surface; its Cauchy horizon exhibits “mass inflation” ; its ergosphere leads to a Penrose-like process . A major simplification in (2+1)-dimensions is the absence of propagating gravitational degrees of freedom, which eliminates the need for quantizing the gravitational field. Therefore, all quantum corrections come from the “matter sector”.

In this Letter, we analytically solve the semiclassical Einstein equations sourced by a conformally coupled and massless quantum scalar field on a rotating BTZ space-time. We obtain the quantum-backreacted metric and investigate the quantum effects on the inner horizon, outer horizon and ergosphere, and investigate the possible creation of a speed-of-light surface. To the best of our knowledge, this is the first time that a quantum-backreacted space-time without an event horizon (such as that of a rotating BTZ geometry) is given by 

$$ds^2 = (M - \frac{r^2}{\ell^2}) dt^2 - J dtd\theta + \frac{dr^2}{r^2 - M} + \frac{r^2}{\ell^2} d\theta^2,$$

where $t \in (-\infty, +\infty)$, $r \in (0, \infty)$ and $\theta \in [0, 2\pi)$ and the cosmological constant is given by $\Lambda = -\ell^{-2}$. The BTZ geometry corresponds to either a black hole or to a naked singularity possessing mass $M$ and angular momentum $J$. The metric is stationary and axially symmetric, with corresponding Killing vectors $\xi \equiv \partial/\partial t$ and $\psi \equiv \partial/\partial \theta$, respectively.

In the case of the rotating BTZ black hole, $M \geq |J|$ (the extremal case corresponding to the equality), the identification Killing field is a noncompact spacelike field – see Eq. below. The resulting black hole space-time possesses an inner (Cauchy) horizon at $r = r_{-} = \ell |\alpha_{-}|/2$ and an outer (event) horizon at $r = r_{+} = \ell \alpha_{+}/2$, where

$$\alpha_{\pm} \equiv \sqrt{M + \frac{J}{\ell}} \pm \sqrt{M - \frac{J}{\ell}}. \tag{2}$$

The inner horizon is classically unstable in a similar manner to that of Kerr or Reissner-Nordström space-times. Unlike Kerr, the 2+1 black hole possesses no curvature singularities but it does possess a causal singularity at $r = 0$: there are inextendible incomplete geodesics that hit $r = 0$. The Killing vector $\xi$ is time-like for $r > r_{SL} \equiv \sqrt{M\ell}$, is null at $r = r_{SL}$ and is space-like for $r \in (r_{+}, r_{SL})$. This means that no static observers can exist for $r < r_{SL}$. The hypersurface $r = r_{SL}$ is hence called the static limit surface and the region $r \in (r_{+}, r_{SL})$ is called the ergosphere. In its turn, the Killing vector $\chi \equiv \xi + \Omega H \psi$, where $\Omega H = J/(2r_{+}^2)$ is the angular velocity of the event horizon, is the generator of the event horizon. The vector $\chi$ is null at the event horizon and, in the nonextremal case, is timelike everywhere outside. This means that, in the nonextremal case, observers that rigidly rotate at the angular velocity of the black hole can exist anywhere outside the event horizon, i.e., there is no speed-of-light surface. In the extremal case, on the other hand, the Killing vector $\chi$ is null everywhere on and outside the event horizon.

---

1 In the nonrotating case, the quantum-backreacted metric has been obtained for a background BTZ black hole in and for a background naked singularity space-time in.

2 We are choosing units such that the gravitational constant is $G = 1/8$ and the three-dimensional Planck’s length is $l_P = \hbar G$. 
For $M\ell \leq -|J|$ the metric describes a conical singularity, also obtained by an identification in CAdS by a spacelike Killing vector, which in this case is compact. Note that Eq. (2) implies that, in this case, $\alpha_{\pm}$ are both purely imaginary: no horizon is present and the geometry is a true naked singularity. In this geometry, $\xi$ is always timelike and so there is no ergosphere. The extremal case corresponds to maximal rotation, $M\ell = -|J|$.

Finally, we note that in the nonextremal cases, $|M|\ell > |J|$, the classical solutions can be obtained by boosting the corresponding static ($J = 0$) black hole or conical solution.

**Backreacted geometry.** The backreaction of quantum matter onto the geometry can be calculated via the semiclassical Einstein equations:

$$G_{\mu\nu} - \ell^{-2} g_{\mu\nu} = \pi \langle T_{\mu\nu} \rangle. \tag{3}$$

Here, $G_{\mu\nu}$ is the Einstein tensor for the quantum-backreacted metric $g_{\mu\nu}$ and $\langle T_{\mu\nu} \rangle$ is the renormalized expectation value of the stress-energy tensor (RSET) of the matter field in some quantum state. The quantum state is determined by imposing boundary conditions for the field on the AdS boundary: the timelike hypersurface $r = \infty$. We note that the RSET is calculated on the classical space-time, rather than on the quantum-backreacted one (with metric $g_{\mu\nu}$).

We shall consider a conformally coupled and massless scalar field satisfying “transparent” boundary conditions on the AdS boundary. Transparent boundary conditions correspond to decomposing the scalar field using modes which are smooth on the entire Einstein static universe. We calculate the vacuum expectation value for the RSET of the scalar field in a state corresponding to transparent boundary conditions in the following way. We consider the BTZ geometry as obtained from the appropriate identification of points in CAdS under an element of the Lorentz group. We then apply the method of images to find the two-point function of the field equation in the BTZ geometry from that in CAdS with the appropriate identification. We then obtain the RSET from the two-point function in the standard way.

We choose the following form for a general, stationary and axisymmetric metric

$$ds^2 = (-e^{2a} + r^2 k^2)dt^2 + 2r^2 kdt d\theta + \frac{dr^2}{b} + r^2 d\theta^2, \tag{4}$$

for some functions $a(r)$, $b(r)$, and $k(r)$, which are given by their classical values plus corrections of order $O(l_P)$, denoted by $a_1$, $b_1$ and $k_1$ respectively. The (potential) horizons are determined by the zeros of $b(r)$ which, to order $l_P$, is $b(r) = (r^2/f^2) - M + (J^2/(4r^2)) + l_P b_1(r)$. Next, we solve the semiclassical Einstein equations in the left hand side, we insert the metric ansatz Eq. (4) and expand to $O(l_P)$; in the right hand side, we insert the RSET derived as indicated above. In order to integrate Einstein’s equations, we fix the coordinate choice so that the values at infinity of the (rescaled) lapse and shift functions are equal to, respectively, 1 and 0, following the choice made in for the classical unperturbed metric. The remaining two integration constants are the mass $M$ and angular momentum $J$, which, in order to make a significant comparison, we assume to have the same values as in the unperturbed solution.

In this way, we find analytic expressions for $a_1$, $b_1$ and $k_1$, which we give elsewhere. In particular, we find that, at large distances, the quantum corrections decay as: $a_1 = O(r^{-3})$, $b_1 = O(r^{-1})$, $k_1 = O(r^{-3})$. In the static limit ($J = 0$, $\alpha_{\pm} = 0$, $\alpha_\parallel = 2\sqrt{M}$), we recover the known results: $a_1 = 0$, $b_1 = O(1/r)$, $k_1 = 0$. Specifically, we find the metric coefficient $b_1(r)$ to be of the form:

$$b_1 = -\sum_{n=1}^{N} \frac{F_n(r)}{a_n(r)\sqrt{r}}, \tag{5}$$

where $N = \infty$ in the black hole case and is finite in the naked singularity case. Here, $F_n(r)$ is a function that for large $r$ grows as $r^2$ and $a_n(r)$ is the squared geodesic distance between a point and its nth image under the identification in CAdS; it can be written as $a_n(r) = D_n r^2 + E_n$ for some coefficients $D_n$ and $E_n$.

**Horizons and other regions of the black hole geometry.** We next investigate various geometrical regions of interest of the backreacted rotating black hole metric. For the black hole, the upper summation bound $N = \infty$ and for fixed $r > r_-$, where $a_n(r) > 0$, this is a converging geometric series. The metric perturbations diverge for $a_n(r_n) = 0$, which occurs for certain discrete radii satisfying $0 < r_n < r_-$. As $n \to +\infty$, $r_n \to r_-$, and therefore the inner horizon becomes a surface with an accumulation of points where $a_n = 0$. This is a direct consequence of the identification that produces the spinning black hole. The Killing vector that is employed in this identification is

$$\zeta(r_+, r_-) = r_+ J_{12} - r_- J_{03}, \tag{6}$$

whose norm, $\zeta \cdot \zeta = r_+^2 - r_-^2$, is positive for a nonextremal black hole. The spacelike vector $\zeta(r_+, r_-)$, however, can identify two distinct points connected by a null geodesic in the CAdS, turning this curve into a closed null solution of the geodesic equation in the black hole geometry. (We note that this curve is not everywhere future directed, as opposed to the closed timelike curves that would be produced if the identification in CAdS was made with a timelike Killing vector: those curves would be everywhere future directed or everywhere past directed). The resulting null closed curve extends from infinity to some radius $r_{min}$ inside the inner horizon and back to infinity. This means that this geodesic is not a serious issue in classical physics because no real massless 3 The SO(2, 2) generators are $J_{ab} = x_a \partial_b - x_b \partial_a$, see e.g., [34].

The backreacted radius of the outer horizon is given by the largest positive root of $b(r) = 0$. Working at $O(l_p)$, the corrected event horizon radius (in the nonextremal case) is of the form $r_+^{(q)} = r_+ + 1 + l_p x_+$, where

$$x_+ \equiv \frac{-2b_1(r_+)}{\alpha_+^2 - \alpha_-^2}, \tag{7}$$

and $b_1(r_+)$ is negative. Therefore, the event horizon grows, $r_+^{(q)} > r_+$. We note that the expression for $r_+^{(q)}$ via Eq. (7) is only valid for $l_p \ll (r_+ - r_-)$. In the opposite regime, $0 < (r_+ - r_-) \ll l_p$, the correction to the horizon radius has an expression different from Eq. (7) [52]. In the extremal case, $r_+ = r_-$, and for $r_+^{(q)} \gg l_p b_1(r_+)$, this expression takes the form $r_+^{(q)} = r_+ (1 + \sqrt{l_p y_+})$, where

$$y_+ \equiv \sqrt{-\frac{b_1(r_+)}{2M}} \tag{8}$$

and

$$b_1(r_+) = -\frac{1}{l_p} \sum_{n=1}^{\infty} \frac{1}{n^2 \sinh \left( \frac{n\pi}{\alpha_+^2} \right)}. \tag{9}$$

This limit coincides with the corrected $r_+^{(q)}$ for the extremal solution in the semiclassical approximation.

To find the boundary of the quantum-corrected ergosphere we need to solve $g_{tt} = -e^{2a(r)} b(r) + r^2 k^2(r) = 0$, which we solve to $O(l_p)$. We analytically find that the sign of the quantum correction to the radius of the static limit surface is always positive.

We can also compute the quantum-corrected angular velocity of the black hole: $\Omega_H^{(q)} = \frac{\partial}{\partial \phi_0} \bigg|_{r_+} = -k(r_+)$. We find numerical evidence that $\Omega_H^{(q)}$ is always positive. We now turn to investigating the speed-of-light surface. The Killing vector $\chi^{(q)\mu}$, in the nonextremal case, is timelike in the near-horizon region and becomes null on the horizon. Near infinity we find that $\chi^{(q)\mu} \sim -\frac{r^2}{\ell^2} (1 - \ell^2 \Omega_H^{(q)2})$. The condition for $\chi^{(q)}$ to be space-like, and (likely) for the space-time to develop a superradiant instability is $\Omega_H^{(q)} = \ell \left( \frac{\ell_2}{2e^{2a(r_+)} - l_p k_1(r_+)} \right) > 1$.

We find that $\Omega_H^{(q)} < \ell \Omega_H \leq 1$ (the equality being realized in the extremal case). We conclude that the quantum effects do not appear to change the superradiant-stability property of the classical solutions.

Another important (and delicate) case is the extremal limit $\alpha_+ \to \alpha_-$. In this case, the identification that yields the extremal black hole, $\zeta_{ext} = r_+ (J_{01} - J_{23}) + (J_{12} + J_{03} + J_{02} - J_{13})/2$, is not obtained as the limit $r_+ \to r_-$. and therefore it is not immediately obvious what happens in this case. However, we obtain that the extremal limit of the RSET in the nonextremal black hole is equal to the RSET in the extremal black hole; the backreacted metrics share the same feature. Therefore, our results are physically meaningful for nonextremal black holes all the way down to the extremal limit.

**Naked singularity and Cosmic Censorship.** For the nonextremal conical singularity ($M \ell < -|J| \leq 0$), the upper summation bound $N$ is finite and, therefore, convergence is not an issue. In this case, the quantum correction $b_1$ possesses at least one pole at a finite radius where $b_1 \to -\infty$. This implies that the quantum corrections always generate an event horizon that covers the conical singularity at $r = 0$. We note, however, that for finite values of $(M, J)$, the formed horizon has size $O(l_p)$ and our results are at most indicative (higher-order quantum corrections are equally important for establishing its presence). Instead, for masses just below $M = 0$, and as in the static case, $r_+ = O(l_p^{1/3})$ appears to be physically meaningful [29]. An alternative way of seeing this is by noting that the metric components as well as the corrections for $a$, $b$ and $k$ are continuous and analytic in the $M$-$J$ plane for $|J| < |M| \ell$. Since in the static case the quantum corrections give rise to a horizon at finite radius [29], the addition of angular momentum produces a continuous change in this radius, and therefore, Cosmic Censorship continues to be upheld when angular momentum is switched on [30].

**Discussion.** We have established that the presence of a conformally coupled quantum scalar field on a rotating BTZ black hole leads to: (1) the event horizon growing ($r_+^{(q)} > r_+$), (2) the radius of the static limit surface growing ($r_{SL}^{(q)} > r_{SL}$), (3) the angular velocity diminishing ($\Omega_H^{(q)} < \Omega_H$), and (4) no evidence that a speed-of-light surface forms. In particular, in the extremal case, the generator of the horizon goes from being null to timelike everywhere outside the horizon, and so, in a sense, “the quantum corrections take the solutions away from extremality”.

The perturbative correction shows the formation of a
singularity at the inner horizon, which can be interpreted as an instability due to the existence of a curvature singularity there. In the extreme case, the event horizon also grows and the curvature singularity still forms inside, so that the black hole can no longer be called “extremal”.

Strictly speaking, however, the instability at $r_-$ signals a breakdown of the linear approximation itself, and therefore, any statement about the fate of the geometry there can be viewed, at most, as an indicative suggestion. Nevertheless, it can also be argued that the singularity of the RSET is not a perturbative approximation but an exact result due to the existence of closed null curves (which are not everywhere future directed or past directed) in the background geometry. Therefore, the formation of a barrier of infinite energy is a real issue that cannot be dismissed on the grounds that the right hand side of (3) blows up, even if this equation could not provide an expression for the metric in the neighborhood of $r_-$.

As a parallel, we note that, in the case of Kerr, Ref. [7] directly links a classical instability of the region $r / r_-$ under linear field perturbations to the existence of closed-timelike curves in that region.

The only sure way of learning about the space-time geometry near the inner horizon would be to solve the coupled system (3) exactly, in which the two-point function and the RSET are computed in the corrected geometry. In the absence of such a scheme, the best one could achieve is a perturbative procedure where the corrected $\langle T^{(1)}_{\mu\nu}\rangle$ is the input to obtain a first corrected metric, $g^{(1)}_{\mu\nu}$, using (3). Next, this metric could be used to compute a new corrected stress-energy tensor, $\langle T^{(2)}_{\mu\nu}\rangle$, etc.

In the iterative procedure outlined above, there is no need to worry about quantum gravity effects for there are no gravitons in 2+1 dimensions, and therefore, there are no gravitational loop corrections. This is a significant difference with respect to the 3+1 case, where quantum gravity corrections cannot be consistently ignored.

For $\ell M < -|J|$ (and possibly for $\ell M = -|J|$ as well), the classical naked singularity dresses up with a horizon produced by quantum effects, as in the static case. We conclude that quantum mechanics provides a mechanism for Cosmic Censorship for spinning as well as for static conical singularities.
