INTRODUCTION

Pyogenic liver abscess (PLA) is a suppurrative infection of the hepatic parenchyma. It can develop as a complication of abdominal and biliary infections, or following hematogenous bacterial seeding of the liver. It is a rare condition but with significant mortality up to 19% [1,2]. Its diagnostic is based in clinical features and biological findings and confirmed by imaging. If left untreated, the PLA runs a lethal course, so an adequate treatment should be performed. This treatment can be medical (antibiotic) which can be associated with interventional
(percutaneous aspiration or drainage) or surgical treatment.

**METHODS**

This is a retrospective study covering the period from 1 January 2004 until 31 December 2013 conducted in the digestive and visceral surgery department at Sahloul university hospital of Sousse, TUNISIA.

We report a series of 34 cases over 10 years. The diagnosis was made on clinical, biological and imaging data.

The treatment was either medical (antibiotic), interventional (percutaneous drainage) or surgical.

Clinical, biological, radiological, therapeutic and evolutive data were collected from the records of inpatients.

**RESULTS**

This study included 19 men and 15 women (sex ratio=1.26). The mean age was 64 years (range 21-85). Forty seven percent of patients were holders of cardiovascular problems (hypertension, dylipidemia, coronary artery disease ...) \( (n=16) \), 29.4% \( (n=10) \) had diabetes, 26.5% \( (n=9) \) were operated for a cholecystitis or angiocholitis and had either only cholecystectomy \( (n=3) \) or cholecystectomy with biliodigestive anastomosis \( (n=6) \), 14.7% \( (n=5) \) were operated for a gastric or duodenal ulcer and one case had appendicectomy 30 days ago.

The mean delay between the onset of the symptoms and the admission was 13.32 days (range 3-30).

Majority of patients \( (94.1\%) \) \( (n=32) \) with pyogenic liver abscess reported upper abdominal pain. High-grade fever or chills were reported in 91.2% \( (n=31) \) of cases, vomiting and nausea in 35.3% \( (n=12) \) of cases, while loss of appetite in 20.6% \( (n=7) \) of cases (Table 1).

On examination, 73.5% \( (n=25) \) of patients were febrile (temperature more than 38°C), tenderness in right hypochondrium or localized guarding were the predominant signs and were found in 91.2% \( (n=31) \) of cases (47.1% and 44.1% respectively), whereas 8.8% \( (n=3) \) of patients were presented with hepatomegaly. About 17.6% \( (n=6) \) of patients presented with jaundice.

Laboratory tests revealed leukocytosis and elevated level of CRP in all cases. In 23.5% \( (n=8) \) patients had hyperbilirubinemia.

Ninety-one percent of patients \( (n=31) \) were investigated by CT scan with or without ultrasound, which showed a positive diagnosis in 100% of cases (Figure 1). Three patients were investigated by only ultrasound which showed a positive diagnosis in one third of cases preoperatively.

Majority of liver abscesses \( [82.4\% \text{ of cases } (n=28)] \) were found in the right lobe of liver. About 11.7% \( (n=4) \) of liver abscesses were confined to the left lobe only. Both lobes were involved in 5.9% \( (n=2) \) of cases. Acute cholecystitis was found in 26.47% \( (n=9) \) of cases and it was the origin of abscesses.

In our series, 79.4% \( (n=27) \) of patients were presented with solitary abscesses. Multiple abscesses were found in 20.6% \( (n=7) \) of cases. The mean size of abscesses was 9 cm (range 3.5 to 20 cm).

Thrombosis of the portal vena or the inferior vena cava as a complication of pyogenic liver abscesses was found in three cases.

Pus culture study was performed in 82.35% \( (n=28) \) of cases of which 21 reports came with positive microbial reports. Here, 28.57% \( (n=6) \) of cases were positive for Escherichia coli and 23.80% \( (n=5) \) shown Klebsiella. Other organisms were Bacteroides in 9.5% \( (n=2) \), Staphylococcus in 4.76% \( (n=1) \), and Streptococcus in 4.76% \( (n=1) \). Polymorphic bacterial flora was found in 19% of cases \( (n=4) \).

Of all the pyogenic liver abscesses, 47% were biliary tract in origin \( (9 \text{ cases of cholecystitis}, 6 \text{ cases of angiocholitis}, \text{one case of intraductal papillary mucinous neoplasm (IPMN)}) \). The rest were cryptogenic in 41%, portal pyemia (appendicitis and diverticulitis) in 6%, or hematogenous (urinary infection) in 6% of cases.

All of patient had received intravenous antibiotic therapy (cephalosporin or fluoroquinolones combination with metronidazole and aminoglycoside) but only two patients were healed by this regime (one case was poorly collected abscess and the other was disseminated abscesses). The mean duration of intravenous antibiotic therapy was 15.5 days (range 5 to 30 days).

The percutaneous drainage (PCD) (Figure 2) was performed in 50% \( (n=17) \) of cases and was successfully in about 70% of cases (we had resort for surgical management in only 5 cases: 3 cases the abscess was localized in the segment VII or VIII of liver and the catheter was blocked or dislodged, one case the abscess was...
| Observation | Age (years); Sex; Past history | Clinical Manifestations | Laboratory Tests | Imaging | Treatment | Bacteriology | Outcome |
|-------------|--------------------------------|------------------------|------------------|---------|-----------|--------------|---------|
| Patient 01  | 79; M                          | Fever + pain in the right upper-quadrant for 5 weeks. O/E: T°=39°C; gardening at palpation of the right upper-quadrant. | Leukocytes: 10700 CRP:252 Hepatic cytolysis | Ultrasound and CT scan: solitary abscess (13 cm, segment VII) | Antibiotic therapy, Percutaneous drainage: failed Surgical drainage. | Pus culture: E. coli | Good. Hospitalization = 30 days |
| Patient 02  | 45; M                          | Fever + pain in the right upper-quadrant for 3 weeks. O/E: T°=37.5°C; gardening at palpation of the right upper-quadrant. | Leukocytes: 14000 CRP:5% Hepatic cytolysis and cholestasis | Ultrasound and CT scan: solitary abscess (segment VII) with thrombosis of inferior vena cava | Antibiotic therapy. Percutaneous drainage. | – | Good. Hospitalization = 45 days |
| Patient 03  | 82; M                          | Fever + right upper-quadrant and epigastric pain for 10 days. O/E: T°=38.7°C; gardening at palpation of the right upper-quadrant with jaundice. | Leukocytes: 15000 CRP:150 cholestasis | Ultrasound and CT scan: multiple abscess of liver with cholecystitis | Antibiotic therapy. Surgical drainage and cholecystectomy. | – | Death after 10 days (septic shock) |
| Patient 04  | 81; M, cholecystectomy with biliodigestive anastomosis for angiocholitis | Fever + right upper-quadrant and epigastric pain for 3 weeks. O/E: T°=37.7°C; gardening at palpation of the right upper-quadrant. | Leukocytes: 13400 CRP: 83 | Ultrasound and CT scan: solitary abscess (6 cm, segment IV). | Antibiotic therapy. Percutaneous drainage. | Pus culture: Bacteroides | Good. Hospitalization= 15 days |
| Patient 05  | 85; F, hypertension; cholecystectomy with biliodigestive anastomosis for angiocholitis | Fever + vomiting and epigastric pain for 5 days. O/E: T°=37.5°C, tenderness at palpation of the right upper-quadrant. | Leukocytes: 13800 CRP: 191 | Ultrasound and CT scan: solitary abscess (6 cm, segments V-VI) | Antibiotic therapy. Percutaneous drainage. | Pus culture: E. coli | Good. Hospitalization= 20 days |
| Patient 06  | 31; M, duodenal ulcer none operated. | Fever + vomiting and epigastric pain for 3 weeks. O/E: T°=37.7°C; tenderness at palpation of the right upper-quadrant. | Leukocytes: 13700 CRP: 469 | Ultrasound and CT scan: multiple abscess of liver (segments V-VII and VIII) | Antibiotic therapy. Percutaneous drainage. | Pus culture: negative | Good. Hospitalization= 6 days |
| Patient 07  | 76; F, hypertension; diabetes, dyslipidemia, cholecystectomy | Fever + right upper-quadrant pain for 2 weeks. O/E: T°=38.7°C; gardening at palpation of the right upper-quadrant. | Leukocytes: 12200 CRP: 65 | Ultrasound and CT scan: multiple abscess of liver (segments V-VI) with cholecystitis | Antibiotic therapy. Percutaneous drainage: failed Surgical drainage+ cholecystectomy. | Pus culture: negative | Good. Hospitalization= 45 days |
| Patient 08  | 69; F, hypertension; diabetes | Fever + right upper-quadrant and epigastric pain for 7 days. O/E: T°=39.2°C; gardening at palpation of the right upper-quadrant. | Leukocytes: 15300 CRP: 265 | Ultrasound and CT scan: solitary abscess of liver (7.5 cm, segment IV) with cholecystitis | Antibiotic therapy. Surgical drainage and cholecystectomy. | Pus culture: negative | Good. Hospitalization= 15 days |
| Patient 09  | 58; F, hypertension; diabetes, dyslipidemia 75; M, cholecystectomy with biliodigestive anastomosis for angiocholitis | Fever + total abdominal pain for 10 days. O/E: T°=59°C; total abdominal tenderness at palpation of the right upper-quadrant. | Leukocytes: 16500 CRP: 394 Hepatic cytolysis | CT scan: solitary abscess of liver (segment VIII) | Antibiotic therapy. Percutaneous drainage: failed Surgical drainage. | Pus culture: Klebsiella | Good. Hospitalization= 60 days |
| Patient 10  | 43; M, appendicectomy 3 weeks ago. | Fever + right upper-quadrant pain for 7 days. O/E: T°=38.9°C; gardening at palpation of the right upper-quadrant and epigastria. | Leukocytes: 15000 CRP: 94 | Ultrasound and CT scan: solitary abscess of liver (9 cm, segment IV-V) | Antibiotic therapy. Pericutaaneous drainage. | Pus culture: Bacteroides | Good. Hospitalization= 17 days |
| Patient 11  | 43; M, appendicectomy 3 weeks ago. | Fever + right upper-quadrant pain for 5 days. O/E: T°=39°C; painful mass at palpation of the right upper-quadrant with jaundice. | Leukocytes: 9400 CRP: 172 | Ultrasound and CT scan: solitary abscess of liver (9 cm; segment V-VIII) | Antibiotic therapy alone for 19 days. | – | Good. Hospitalization= 12 days |
| Patient 12  | 70; F                          | Fever + right upper-quadrant + vomiting for 3 weeks. O/E: T°=39°C; painful mass at palpation of the right upper-quadrant with jaundice. | Leukocytes: 10200 CRP: 279 Hepatic cytolysis and cholestasis | Ultrasound and CT scan: solitary abscess of liver (5 cm; segment V) with cholecystitis | Antibiotic therapy. Surgical drainage and cholecystectomy. | Pus culture: negative | Good. Hospitalization= 8 days |

| Patient 31  | 72; M | Fever+ right upper-quadrant and epigastric pain for 2 weeks. O/E: T°=39°C; tenderness at palpation the right upper-quadrant. | Leukocytes: 9300 CRP: 108 | Ultrasound and CT scan: solitary abscess of liver (segment V) with cholecystitis. | Antibiotic therapy. Surgical drainage and cholecystectomy. | Pus culture: Klebsiella. | Good. | 15 days |
| Patient 32  | 61; F; cholecystectomy with biliodigestive anastomosis. | Right upper-quadrant and epigastric pain for 7 days. O/E: T°=37.5°C; gardening at palpation of the right upper-quadrant. | Leukocytes: 9200 CRP: 182 | CT scan: solitary abscess of liver (segment VI) intraductal papillary mucinous neoplasm. | Antibiotic therapy. Surgical drainage. | Pus culture: Polymorphic bacterial flora. | Good. | 21 days |
| Patient 33  | 69; F; hypertension cholecystectomy. | Right upper-quadrant pain; vomiting for 3 weeks. O/E: T°=37.7°C; gardening at palpation the right upper-quadrant and epigastria with jaundice. | Leukocytes: 13100 CRP: 320 Hepatic cytolysis and cholestasis | Ultrasound and CT scan: solitary abscess of liver (6 cm; segment IV). | Antibiotic therapy. Percutaneous drainage. | Pus culture: E. coli | Good. | 22 days |
| Patient 34  | 57; F; hypertension; diabetes; dyslipidemia. | Fever+ right upper-quadrant pain +vomiting with anorexia for 4 weeks. O/E: T°=39°C; tenderness at palpation the right upper-quadrant. | Leukocytes: 13500 CRP: 183 | Ultrasound and CT scan: solitary abscesses of liver (12 cm; segment IV) with cholecystitis. | Antibiotic therapy. Surgical drainage and cholecystectomy. | Pus culture: Polymorphic bacterial flora. | Good. | 19 days |
disseminate and in the other case the abscess was associated with a cholecystitis). The mean size of abscess in the percutaneous drainage group was 8.7 cm (3.5 to 15 cm) and in more than 82% (n=14) of cases abscess was solitary.

Surgery was performed in 58.82% (n=20) of cases. Six patients had only surgical drainage of abscess and the other 14 patients had cholecystectomy with drainage of abscess (because of associated cholecystitis in 9 cases, gallbladder stone in 2 cases, or because the abscess involved segment V of liver in 3 cases).

The mean length of hospital stay was 19.7 days (range 6 to 62 days).

The outcome was generally favorable with the exception of one death from septic shock.

**DISCUSSION**

Pyogenic liver abscess is a rare but life threatening disease with the reported incidence ranging from 446 per 100,000 hospital admissions in some locations to 22 per 1,000,000 hospital admissions in others [10,11,13]. In our series, the sex-ratio was 1.26 and confirmed the male predominance in many studies, for example Ali et al and Mangukiy et al had sex-ratio 1.5 and 4 respectively [4,10]. Historically, liver abscess developed in young, otherwise healthy patients with an intra-abdominal infection. Ochsner et al and Mangukiy et al reported a peak incidence in the fourth decade [14], but there is a gradual trend of increase in the age of patients with liver abscess, probably due to aggressive treatment of acute appendicitis and other intra-abdominal infections of the young which prevents the abscess from occurring which corresponded to the findings of Ali et al and our series (mean age 56 years and 64 years respectively).

Patients who are immunocompromised or diabetic are especially prone to developing pyogenic liver abscess; diabetic persons have a 3.6 fold increased risk for developing pyogenic liver abscess compared with the general population [15]. In our series, 47% of patients were holders of cardiovascular problems and 29.4% had diabetes.

Ochsner et al and Norman et al [16] showed that clinical features of pyogenic liver abscess were non-specific. Many authors [4,6,8,13] reported that the most significant features of clinical findings of pyogenic liver abscesses were upper abdominal pain with high grade fever and hepatomegaly as reported by our series.

In our series, laboratory tests revealed leukocytosis and elevated level of CRP in all cases and 23.5% of patients had hyperbilirubinaemia. Mangukiya et al found total leukocytic count more than 11,000 in 78% of cases and hyperbilirubinemia in 12.5% of cases.

Consistent with other studies, CT scan was more sensitive than ultrasonography in the detection of liver abscesses, with 100% being clearly identified by CT scan [10,11,13]. Pyogenic liver abscess is usually located in the right lobe of the liver as reported by our study. This predilection for the right lobe can be explained anatomically. The right hepatic lobe receives blood from the superior mesenteric vein via the right portal vein, whereas the left lobe receives inferior mesenteric and splenic drainage (There is a preferential blood supply to the right hepatic lobe through the large right branch of portal vein). It also contains a denser network of biliary canaliculi and, overall, accounts for more hepatic mass [10,12,13]. In our study, PLA was solitary in the majority of cases, the same findings was reported by Ali et al and Mangukiy et al [4,10] (54% and 56% respectively).

Inferior vena cava and/or hepatic vein thrombosis are infrequent but life-threatening complications of liver abscess. Budd Chiari syndrome or pulmonary embolism could cause rapid deterioration of these patients. Usually, it has been reported only in adult patients of amebic liver abscess but BAGRI et al reported a case of inferior vena caval and right atrial thrombosis complicating pyogenic liver abscess in a young child [17,18]. In our study, 3 cases of thrombosis of the portal vena or the inferior vena cava as a complication of pyogenic liver abscesses were reported.

Etiologically, PLA could have as origin a biliary tract, pyogenic, portal pyemia or hematogenous origins. Consistent with our study, Ali et al found that the most common etiologies were biliary in 42% of cases then pyogenic in 35% of cases and portal pyemia in 13%, but Mangukiy et al found that 56% of the total abscesses were pyogenic in origin, while 15.5, 15, and 13.5% were of biliary, portal, and hematogenous in origin, respectively. Although it has been suggested that pyogenic liver abscess is a sign of occult gastrointestinal malignancy, for that a screening colonoscopy should be performed in patients with pyogenic liver abscess [17].

Gram negative aerobes are found to be the major abscess pathogens in pyogenic liver abscess. *E. coli* is the most common pathogen in most of European studies, but in USA and Asian countries, other distributions are seen with high proportions of Klebsiella spp. (Especially, the highest incidence in Taiwan that ranges from 80% to 90% and a relatively low incidence of 30%-40% is estimated in the US). Diabetes has been found to be an important risk factor for Klebsiella liver abscess (KLA); up to 75% of patients with KLA in Asia have diabetes [6,15,18,19]. In our study, pus culture study was performed in 28 cases of which 21 reports came with positive microbial reports (28.57% of cases were positive for Escherichia coli and 23.80% (n=5) shown Klebsiella of which 3 patients had diabetes. Other organisms were Bacteroides in 9.5%, Staphylococcus in 4.76% and Streptococcus in 4.76%. Polymorphic bacterial flora was found in 19% of cases).

In the past, liver abscesses were considered a clear indication for surgical drainage. In recent years, a more conservative approach has been adopted and needle aspiration or percutaneous continuous catheter drainage in combination with parenteral antibiotics is considered the gold standard treatment [4,10,13,20,21]. The most commonly used antibiotics were fluoroquinolones, the third-generation cephalosporins with metronidazole and an aminoglycoside [4,19,22]. Other combinations are proposed. The optimal duration intravenous therapy, as well as the duration of subsequent oral therapy, remains unclear. In the study of Taiwan, therapy generally consisted of 3 weeks of intravenous antibiotics followed by 1-2 months of oral therapy [20]. However, a US study in 2004 indicated shorter courses of antibiotic therapy with durations of intravenous therapy of 17.5 days, and oral therapy of 13.6 days which were associated with extremely low mortality [23]. This antibiotic therapy can be curative alone, in Mangukiy’s study, 32% of patient were improved completely by antibiotic medication alone. In our study, all of patient had received intravenous antibiotic therapy (cephalosporin or fluoroquinolones combination with metronidazole and aminoglycoside) but only two patients were improved completely by this regime. The mean duration of intravenous antibiotic therapy was 15.5 days (range 5 to 30 days).

Percutaneous drainage has the advantages to simplify the treatment and avoid a general anesthesia and laparotomy; in addition, it can be helpful in determining the causative organisms and can shorten the duration of treatment. It includes percutaneous aspiration or percutaneous catheter drainage. Yu et al found that intermittent needle aspiration was probably as effective as continuous catheter drainage for the treatment of PLA [20]. It’s indicated in following situations [17]: (1) Patients who continued to be febrile even after 48-72 h of adequate medical treatment; (2) Liver abscess more than 6 cm in size; (3) Clinical or ultrasonographic features suggesting impending perforation.
Success rate of percutaneous drainage is more than 90%. It has a low rate of complications which include hemorrhage, perforation of hollow viscera, peritoneal spillage, catheter displacement or blockage, and sepsis. Although complications of PCD are infrequent, the sequel can be serious therefore PCD should be performed under active monitoring of vital sign[2]. In our study, percutaneous drainage was performed in 50% of cases and success rate was about 70%. The mean size of abscess in the percutaneous drainage group was 8.7 cm and in more than 82% of cases abscess was solitary. In the study of Mangukiya, among the catheter group, 91.66% of patients had solitary large abscess and the mean size of abscess was 11.5 cm.

Surgery drainage is carried out in patients falling within the criteria which are as follows[19]: (1) Thick pus which could not be aspirated; (2) Patients with multiple liver abscesses; (3) Patients with ongoing sepsis even after antibiotic therapy and percutaneous drainage; (4) Patients with underlying diseases such as the biliary tract disease or the liver cirrhosis; (5) Multiloculated abscess; (6) Abscess in the left lobe; (7) Ruptured abscesses.

In our study, surgery was performed in 58.82% of cases because of biliary tract disease associated, multiple liver abscesses, left localization of abscess, or failure of PCD. Six patients had only surgical drainage of abscess and the other 14 patients had cholecystectomy with the drainage of the abscess.

In general, surgical drainage has been reserved for patients who fail to respond to treatment with percutaneous drainage and antibiotics or who have concurrent intra-abdominal pathology which requires surgical management. Thus, percutaneous and surgical techniques are not competing methods, but they have different indications, and surgery also represents an option for non-responders to percutaneous treatment[20].

The mean length of hospital stay was 19.7 days (18.4 days for the PCD group, 20.36 days for the surgical management group and 21 days for the patients who are treated by antibiotic therapy alone). Ali et al report a mean length of hospital stay of 20±22 days (range: 1-82 days)[19].

The outcome was generally favorable and the mortality rate in developed countries ranges from 2 to 12% and can be up to 19% in some series[12]. Mangukiya et al and Ali et al report a rate of 1.5% and 2% respectively[4,5], in our study the rate was 3%.

CONCLUSION

PLA is a rare condition but has undergone a huge change. It affects the subjects increasingly older. Bacteriologically, there is an emergence of Klebsiella pneumoniae which is as follows

1. Patients with multiple liver abscesses;
2. Patients with ongoing sepsis even after antibiotic therapy and percutaneous drainage;
3. Patients with underlying diseases such as the biliary tract disease or the liver cirrhosis;
4. Multiloculated abscess;
5. Abscess in the left lobe;
6. Ruptured abscesses.

The mean size of abscess in the percutaneous drainage group was 8.7 cm and in more than 82% of cases abscess was solitary. In the study of Mangukiya, among the catheter group, 91.66% of patients had solitary large abscess and the mean size of abscess was 11.5 cm.

Surgery drainage is carried out in patients falling within the criteria which are as follows[19]: (1) Thick pus which could not be aspirated; (2) Patients with multiple liver abscesses; (3) Patients with ongoing sepsis even after antibiotic therapy and percutaneous drainage; (4) Patients with underlying diseases such as the biliary tract disease or the liver cirrhosis; (5) Multiloculated abscess; (6) Abscess in the left lobe; (7) Ruptured abscesses.
