ABSTRACT Although much work on the biochemistry of the key enzymes of bacterial perchlorate reduction, chlorite dismutase, and perchlorate reductase has been published, understanding of the molecular mechanisms of this metabolism has somewhat hampered by the lack of a clear model system amenable to genetic manipulation. Using transposon mutagenesis and clean deletions, genes important for perchlorate reduction in *Azospira suillum* PS have been identified both inside and outside the previously described perchlorate reduction genomic island (PRI). Transposon mutagenesis identified 18 insertions in 11 genes that completely abrogate growth via reduction of perchlorate but have no phenotype during denitrification. Of the mutants deficient in perchlorate reduction, 14 had insertions that were mapped to eight different genes within the PRI, highlighting its importance in this metabolism. To further explore the role of these genes, we also developed systems for constructing unmarked deletions and for complementing these deletions. Using these tools, every core gene in the PRI was systematically deleted; 8 of the 17 genes conserved in the PRI are essential for perchlorate respiration, including 3 genes that comprise a unique histidine kinase system. Interestingly, the other 9 genes in the PRI are not essential for perchlorate reduction and may thus have unknown functions during this metabolism. We present a model detailing our current understanding of perchlorate reduction that incorporates new concepts about this metabolism.

IMPORTANCE Although perchlorate is generated naturally in the environment, groundwater contamination is largely a result of industrial activity. Bacteria capable of respiring perchlorate and remediating contaminated water have been isolated, but relatively little is known about the biochemistry and genetics of this process. Here we used two complementary approaches to identify genes involved in perchlorate reduction. Most of these genes are located on a genomic island, which is potentially capable of moving between organisms. Some of the genes identified are known to be directly involved in the metabolism of perchlorate, but other new genes likely regulate the metabolism in response to environmental signals. This work has uncovered new questions about the regulation, energetics, and evolution of perchlorate reduction but also presents the tools to address them.

Over billions of years, bacteria have evolved the ability to reduce dozens of different electron acceptors as part of their energy metabolism, from widely distributed molecules, such as oxygen, nitrate, and sulfate, to more esoteric compounds, like perchlorate. Naturally occurring perchlorate is thought to have an atmospheric origin but is deposited only in very small quantities (1); it accumulates mainly in hyperarid environments, such as the Atacama Desert and the Antarctic Dry Valleys (2). Anthropogenic perchlorate, however, is a by-product of various industries and can lead to localized contamination of groundwater due to its chemical stability and aqueous solubility (3). Despite the sporadic accumulation of perchlorate in the extant terrestrial environment, dissimilatory perchlorate-reducing bacteria (DPRB) are ubiquitous and can be isolated from many different environments (4).

Perchlorate reduction by microorganisms has been observed for decades but was initially thought to be a product of the nitrate reduction machinery common to many eubacteria and archaea (5). Further study of pure-culture DPRB isolates revealed two enzymes specific to this metabolism: perchlorate reductase (PcrAB) and chlorite dismutase (Cld). PcrAB is a heterodimeric molybdoenzyme that belongs to the widespread and functionally diverse dimethyl sulfoxide (DMSO) reductase family (6). PcrAB reduces perchlorate to chlorite, which is then dismutated into chloride and oxygen by the heme-containing Cld (7, 8). The chlorite dismutase gene was initially identified in the chlorate reducer *Ideonella dechloratans* and subsequently in the DPRB *Dechloromonas agitata* CKB (9, 10). In the regions flanking the cld gene in two *Dechloromonas* species, the genes for the molybdopterin-containing perchlorate reductase were found (6). More recently, the entire genomes of several DPRB have been sequenced, and all share a perchlorate reduction genomic island (PRI) that includes *pcrAB* and *cld* in addition to several conserved genes with unknown function (11). Similarly, a comparative study of chlorate reducers found that chlorate reduction genes are associated with composite transposons which contain conserved genes with unknown function (12). These comparative genomic studies pro-
vided further evidence that (per)chlorate reduction genes are transferred horizontally, and several new genes were identified in the PRI that could be involved in regulation of the metabolism (11). Previous efforts to understand the regulation of perchlorate reduction by environmental conditions have used the enzymatic activity of whole cells or extracts, but little is known about the genetic or transcriptional basis for these observations (13, 14).

While continued isolation of novel DPRB provides a diverse collection of bacteria capable of this metabolism (15–17), understanding the basic tenets of perchlorate reduction is hindered by the lack of a robust model system amenable to genetic manipulation. To fill this role, we have selected the betaproteobacterium Azospira suillum PS (formerly known as Dechlorosoma suillum) (18). PS is a facultative anaerobe that is capable of respiring perchlorate and nitrate under anaerobic conditions. It grows rapidly and robustly on rich media, and its genome has been fully sequenced and is publicly available (11, 19). Additionally, its perchlorate-reducing physiology has been studied in the context of environmental regulation (13), chemotaxis (20), and redox cycling of electron shuttles (21, 22).

In this study, we set out to broaden our knowledge about the molecular mechanisms and genetic factors involved in perchlorate reduction. We performed a random transposon mutagenesis of PS and identified 18 mutants unable to grow on perchlorate, most of which contained transposon insertions in the PRI. To further dissect this genomic island, we developed a method for creating markerless deletions and constructed in-frame knockout mutants for the 17 core genes in the PRI. We found that eight were essential for perchlorate reduction, while the remaining nine genes were either partially defective during growth on perchlorate or had no obvious phenotype. As expected, pcrABCD and cld were essential for perchlorate reduction, but some were genes for a response regulator (pcrR), histidine kinase sensor (pcrS), and a PAS domain-containing protein (pcrP), which form a putative regulatory system. Complementation of all eight genes using plasmid-carried copies of the deleted gene resulted in partial or complete restoration of growth via perchlorate reduction. This study expands the list of genes essential for perchlorate reduction but also supplies the tools for further analysis of the genetics and regulation of this metabolism.

RESULTS
Transposon mutagenesis of PS and screening for mutants. Transposon mutagenesis and screening identify the genetic factors involved in the production of a given phenotype in an unbiased manner. We mutagenized PS using a plasmid-based MiniHimar transposon, which was delivered using the conjugation-competent Escherichia coli strain WM3064 (23, 24). Mutants were isolated as single, kanamycin-resistant colonies aerobically on a medium designed to maximize the breadth of genes disrupted during mutagenesis. This medium contained acetate, lactate, and pyruvate as carbon sources and was thus designated ALP media (see Materials and Methods).

To screen the mutants for defects associated with perchlorate reduction, we took advantage of the fact that PS grows rapidly in the presence of both nitrate and perchlorate when transferred from aerobic conditions (Fig. 1). Additionally, when both nitrate and perchlorate are present under anaerobic conditions, nitrate is used in preference to perchlorate by this organism, resulting in a diauxic growth curve (13). The mutant library was screened for growth under these conditions over a 30-h period. Individual mutants that exhibited defects in either growth rate or final optical density were restreaked and selected for further study. To identify mutants with perchlorate-specific defects, each mutant was further characterized for the ability to grow on nitrate, perchlorate, nitrate/perchlorate, and oxygen. Many mutants that were selected for additional characterization displayed wild-type growth characteristics, suggesting that the initial screen had a high incidence of false positives. Some mutants were pleiotropic, suffering defects of various intensities in both growth rate and final optical density under multiple conditions. In order to focus on mutants directly involved in perchlorate reduction, we defined a subset of the mutants as “perchlorate null” mutants. These mutants did not grow at all on perchlorate but exhibited normal growth on nitrate alone, as well as normal aerobic growth on both solid and liquid ALP media. The full phenotypic characterizations of the transposon mutants of interest are detailed in Table 1. In total, 18 perchlorate null mutants and 18 pleiotropic mutants were isolated (Table 1).

Transposon mutagenesis highlights importance of genes in the PRI. The genomic locations of transposon insertions were identified using an arbitrary PCR-based method (Table 1). Many pleiotropic mutations in genes predicted to be important for anaerobic respiration, including genes for molybdopterin biosynthesis (moeA and moga), molybdenum uptake (modC), nitrate reduction/denitrification (napA, norD, and Dsui_1177), anaerobic heme biosynthesis (hemN), and ubiquinone biosynthesis (ubiX), were identified. Additionally, three insertions in the rnf operon resulted in wild-type growth on nitrate and oxygen but very slow growth on perchlorate. Similarly, an insertion in a gene from the relA/spoT family (Dsui_2816) was associated with a very low growth rate on perchlorate.

While the pleiotropic mutants had insertions in genes located throughout the chromosome, most (14 out of 18) of the perchlorate null mutant insertions were localized to 8 genes in the PRI (11). Insertions were found in previously identified structural genes (pcrA, pcrB, pcrD, and cld) but also in several genes of un-

(Continued on following page)
known function. Three genes in the PRI identified in this screen encode a putative histidine kinase signal transduction system (HKS). We have named these genes pcrR, pcrS, and pcrP to reflect their linkage with pcrA and the fact that homologs of some or all of these genes can be identified in the PRI of other perchlorate reducers, some of which are distantly related to PS (11). The gene names pcrR, pcrS, and pcrP are intended to be suggestive of the putative roles of each gene product in the HKS: the response regulator, the kinase sensor, and the PAS domain-containing protein. PcrP and PcrS are predicted to be integral membrane proteins with large regions in both the cytoplasm and periplasm. The cytoplasmic region of PcrS contains domains seen in many bacterial histidine kinases: a HAMP linker domain (PF00672), a phospho-acceptor domain (PF00512), and an ATPase domain (PF02518) (25). PcrP contains two PAS domains from different subfamilies in its cytoplasmic region (PF08448 and PF13188) (26). In contrast to the cytoplasmic regions, which are composed of well-characterized and common domains, the periplasmic regions of PcrP and PcrS are not homologous to any domains in the COG or Pfam databases. These regions are fairly large, consisting of approximately 250 and 270 amino acids in PcrS and PcrP, respectively. BLAST-P searches of the PcrP domain against finished genomes identified several similar sequences, while a search using the PcrS domain identified only the PcrS homolog from another DPRB, Dechloromonas aromatica RCB. PcrR contains three domains commonly found in response regulators: the receiver domain (PF00072), a $\phi_5$H interaction domain (PF00158), and a helix-turn-helix DNA-binding domain (PF02954) (27). Another insertion in a perchlorate null mutant mapped to the cupin domain protein gene (Dsui_0153) in the PRI. Outside the PRI, three genes also contained insertions that led to the perchlorate null phenotype. Two separate mutants with insertions in Dsui_0704, TABLE 1 (Continued)

*Transposon mutants were scored “++” if growth was identical to that of the wild type, “++” if growth rate or final optical density was less than that of the wild type, or “0” if no growth was observed.

b CoA, coenzyme A.
although efficiency of integration was low (5 to 10 insertions per tors derived from pNPTS138 were achieved using electroporation, tions could be recovered. Reliable chromosomal insertions of vec- proved to be an unpredictable method of vector delivery, since was able to integrate into the chromosome. However, conjugation would frequently fail and no chromosomal inser- vector derived from pNPTS138 (Dickon Alley, unpublished data) of genes in the PRI. The 17 genes in the PRI are displayed with the locations of transposon insertions that were identified in the screen. The green pins indicate mutants that did not grow on perchlorate, while the red pins indicate mutants that did not grow on perchlorate or on the diauxic medium. Genes are colored by functional group: green genes encode chlorite dismutase and perchlorate reductase components, royal-blue genes are the PRI HKS, red genes are parts of the putative electron transport chain, orange genes are components of a putative oxidoreductase system, and light-blue genes are part of a putative sigma factor/antisigma system.

which encodes the alternative $\sigma_{54}$-type sigma factor RpoN, were isolated. The other two genes (Dsui_0128 and Dsui_1441) are of unknown function.

Two diauxic phenotypes associated with “perchlorate null” mutants. Perchlorate null mutants were defined as having no growth on medium containing perchlorate, while being indistin- guishable from wild-type PS on medium with nitrate. When the 18 perchlorate null mutants were grown on diauxic medium con- taining nitrate and perchlorate, two different phenotypes were observed. Most (15 out of 18) of the perchlorate null mutants had similar growth curves on diauxic medium and nitrate-only me- dium. The remaining three perchlorate null mutants had signifi- cantly impaired growth on diauxic medium relative to that on medium containing only nitrate. Interestingly, all three of these mutants had transposon insertions in cld, the gene encoding chlor- rite dismutase (Fig. 2). The other 15 perchlorate null mutants had insertions in 10 different genes, including pcrA (Fig. 2). To high- light the different diauxic growth phenotypes, pcrA::Himar and cld::Himar transposon mutants were compared to a biotin biosyn- thetic mutant (bioA::Himar) which had wild-type growth charac- teristics on kanamycin-amended ALP medium, presumably due to the presence of biotin in the vitamin supplement (Fig. 3A to C).

Neither the pcrA::Himar nor the cld::Himar mutants grew at all on perchlorate (Fig. 3B), but the cld::Himar mutant grew to a much lower optical density than the pcrA::Himar mutant on nitrate and perchlorate (Fig. 3C).

Developing a genetic system in PS and systematic deletions of genes in the PRI. To confirm that genes identified in the trans- poson screen were essential for perchlorate reduction, we developed a system for making markerless chromosomal deletions in PS. Several different suicide vectors did not undergo chromoso- mal integration when delivered via conjugation, but a suicide vector derived from pNPTS138 (Dicken Alley, unpublished data) was able to integrate into the chromosome. However, conjugation proved to be an unpredictable method of vector delivery, since conjugations would frequently fail and no chromosomal inser- tions could be recovered. Reliable chromosomal insertions of vec- tors derived from pNPTS138 were achieved using electroporation, although efficiency of integration was low (5 to 10 insertions per $\mu$g plasmid DNA transformed). This is consistent with the previ- ous observation that Azospira spp. are resistant to transformation (28).

We used pNPTS138 to create deletions of the 17 genes in the conserved core of the PRI. Because many genes in the PRI are in operons (e.g., pcrABCD), we designed the deletion constructs to create in-frame deletions of each gene that did not disturb the ribosomal binding site or promoters of nearby genes. Once each deletion was made, we characterized the strain’s ability to grow on nitrate, perchlorate, and nitrate plus perchlorate. Of the eight genes in the PRI that were defined as being perchlorate null mu- tants during the transposon screen, seven (pcrABD, cld, and pcrPSR) recapitulated the perchlorate null phenotype. Addition- ally, the deletion of pcrC resulted in a perchlorate null phenotype, although no insertions in pcrC were isolated during the trans- poson screen. When Dsui_0153 was deleted, the resulting strain exhibited no differences from the wild type under all conditions tested, suggesting that the perchlorate null phenotype of Dsui_0153::Himar was the result of a polar effect, possibly on the adjacent pcrP gene.

In addition to Dsui_0153, deletion of six other genes in the PRI also had no apparent phenotype. Five of these genes (Dsui_0154 to Dsui_0158) are situated at one end of the PRI and comprise two oppositely oriented operons. The five genes contain a predicted sigma factor/anti-sigma factor pair, genes homologous to yedYZ from E. coli (29), and a gene encoding a hypothetical protein. The sixth nonessential gene (Dsui_0141) is located at the opposite end of the PRI and is a homolog of moaA, a gene involved in molyb- dopterin biosynthesis (30). Two additional genes in the PRI, Dsui_0143 and Dsui_0144, were not essential for perchlorate re- duction, but both mutants suffered from slight yet significant growth rate defects on perchlorate. Dsui_0144 is predicted to en- code a tetraheme c-type cytochrome homologous to proteins such as NapC, NirT, and CymA, all of which function as quinol dehy- drogenases in electron transport chains involved in the reduction of various electron acceptors (31). Dsui_0143 is predicted to be a gene encoding a protein homologous to EbdC, the gamma sub- unit of ethylbenzene dehydrogenase of Aromatoleum aromaticum, which contains a heme b and forms a heterotrimer with the alpha and beta subunits (32). However, the Dsui_0143 protein may con- tain two additional heme c molecules, since it contains two puta- tive heme c binding motifs (one CXXXH motif and an atypical CWXXC). These two motifs are conserved in the homologous NirB protein, which is encoded in a cluster of genes involved in nitrite reduction in Pseudomonas stutzeri (33). The growth phenotypes for all 17 single deletions are summarized in Table 2.

Complementation of perchlorate reduction mutants. To show that the eight genes from the PRI were independently essential for perchlorate reduction and the observed phenotypes were
not the result of polar effects, we developed a system for complementation analysis. The broad-host-range plasmid pBBR1MCS2 was tested for stable replication in PS and was used as the backbone for all complementation vectors. The complementation vectors were constructed in two groups. The first group contained the genes pcrPSR, which are assumed to be transcribed independently based on their alternating orientation (Fig. 2). When constructing these vectors, we included the ~150-bp sequence upstream of the start codon in order to retain the native promoter and regulation. The second group contains five essential genes (pcrABCD and cld) located in the same operon. To construct these vectors, we first made a plasmid with the pcrA promoter (pRAM62) and then incorporated each of the five genes independently into pRAM62 with their endogenous ribosomal binding site. Each of the eight perchlorate null deletion mutants received both the complementation vector and the empty pBBR1MCS2 vector. Under anaerobic conditions with both nitrate and perchlorate, all eight complemented strains were able to grow on perchlorate, while the strains with the empty vector recapitulated the defective growth curves seen in the deletion mutants (see Fig. S1 to S3 in the supplemental material). The complemented strains had variable lag times when switching from nitrate to perchlorate and different growth rates on perchlorate. The reasons for this are unknown but could be due to differences in expression between the complemented mutants and wild-type PS.

Phenotypic characterization of Δcld ΔpcrA double mutant.
To further explore the discrepancy between the diauxic phenotypes of Δcld and ΔpcrA, we constructed a Δcld ΔpcrA double mutant by electroporating the cld deletion vector into the previously constructed ΔpcrA strain. As previously described, the Δcld strain exhibited normal growth on nitrate alone but was impaired for growth on nitrate when perchlorate was also present (Fig. 4A and B). We hypothesized that this was due to baseline expression of pcrA and accumulation of chlorite in the absence of Cld activity. As expected, the Δcld ΔpcrA strain did not grow on perchlorate but was able to grow normally on nitrate (Fig. 4A and C). However, in the presence of nitrate and perchlorate, the Δcld ΔpcrA mutant recovered the ability to grow on nitrate as did the ΔpcrA single deletion mutant (Fig. 4B).

DISCUSSION
Previous work identified the cld gene by sequencing a fragment of a purified enzyme with chlorite dismutase activity (34). This sequence was used to amplify and sequence cld from Dechloromonas agitata CKB and subsequently used to identify neighboring perchlorate reductases (6, 10). pcrA was directly mutagenized and shown to be essential in Dechloromonas aromatica RCB; however, this was done with an antibiotic cassette insertion and may have resulted in polar effects on nearby genes (6). A forward genetics approach confirmed that cld and pcrA are essential for perchlorate reduction in Azospira suillum PS and also identified the importance of pcrB, pcrD, a new HKS, and rpoN. Markerless in-frame deletion was used to confirm the insertions in the PRI and also led to the identification of pcrC as an essential gene for perchlorate reduction. These complementary genetic approaches advance our understanding of the genetic factors involved in perchlorate reduction and establish Azospira suillum PS as a model perchlorate reducer.

The majority of the genes identified as essential for perchlorate reduction are located in the perchlorate reduction genomic island (PRI), which contains 17 genes in PS that are conserved in Dechloromonas aromatica RCB but not in other closely related organisms incapable of perchlorate reduction (11). Our transposon screen identified cld, pcrA, pcrB, and pcrD as essential for perchlorate reduction, which we confirmed with deletion mutagenesis. Al-
though it was not identified in the transposon screen, pcrC was also found to be essential for perchlorate reduction. pcrB encodes the beta subunit of the perchlorate reductase, and the initial biochemical characterization of perchlorate reductase from Azospira sp. GR-1 identified a stable enzyme complex in an alpha-beta conformation (8). PcrB is likely required for the reductase complex stability and for delivering reducing equivalents from the inner membrane electron transport chain to the active site of PcrA. PcrC is a multiheme cytochrome c that was previously thought to be part of the perchlorate reduction pathway in all DPRB (6), but a recently isolated and described organism, Arcobacter sp. CAB, reduces perchlorate and does not have a gene homologous to pcrC. An emerging paradigm for histidine kinase signal transduction system that is conserved in other DPRB (11). The sensory inputs and physiological outputs of this system are currently unknown, but the DNA-binding domain of PcrR suggests that it likely binds to promoters to modulate transcription. PcrR also contains a sigma54 interaction domain, which can recruit sigma54-type sigma factors to promoters where the regulator is bound and hydrolyze ATP to initiate transcription (39). PS contains exactly one sigma54-type sigma factor, encoded by the rpoN gene (Dsui_0704), which was one of only three genes outside the PRI that resulted in a perchlorate null phenotype when mutated with a transposon insertion. Additionally, there is a conserved promoter region upstream of pcrA that contains an RpoN-binding motif (11). Based on these observations, we hypothesize that at least one of the outputs of this system is to upregulate transcription of the pcrABC operon in an RpoN-dependent manner. The presence of two separate sensor proteins that are both essential (PcrP and PcrS) hints at a complex regulatory mechanism.

The periplasmic domains of PcrP and PcrS are unique, and the signals that modulate this system are unknown. Perchlorate, nitrate, or intermediates of both reductive pathways could be sensed directly, as is the case for the E. coli NarX sensor kinase, which autophosphorylates in response to binding nitrate at the dimerization interface (40). An emerging paradigm for histidine kinase “two-component” signal transduction is the presence of a third auxiliary protein which can adjust the autophosphorylation of the histidine kinase and/or phosphotransfer to the response regulator (41). PcrP could be such an auxiliary protein, and it could sense signals that originate either in the periplasm or in the

**TABLE 2 Annotations of the 17 core PRI genes and phenotypic information based on deletion mutants**

| Locus tag | Gene name | Gene product | Pfam domain(s) | Growth on perchlorate | Growth on nitrate and perchlorate |

*For growth on perchlorate, “++” denotes wild-type growth on perchlorate, “+” denotes growth at a lower rate than that of the wild type, and “0” denotes no growth. For growth on nitrate and perchlorate, “++” denotes wild-type growth, “+” denotes growth only during the initial denitrification phase, and “0” denotes very little growth. All deletion mutants grew identically to the wild type on nitrate alone.*
cytoplasm, perhaps via its two PAS domains. Interestingly, the pcrPSR genes do not appear in the genome of Dechloromonas agitata CKB, a DPRB that does not respire nitrate, unlike PS, suggesting that the PRI HKS could play a role in nitrate-dependent repression of perchlorate reduction (11, 13, 42). We have presented a schematic for the basic functions of the PRI HKS, highlighting the domain structure of PcrP and PcrS in the inner membrane, as well as the putative function of PcrR in initiating transcription in an RpoN-dependent manner (Fig. 5). Although we currently know little about how the system functions, molecular analysis of the signals and domains involved will be crucial in understanding the evolution of the PRI.

Nine genes in the PRI were not required for perchlorate reduction (Dsui_0141, Dsui_0143-Dsui_0144, and Dsui_0153 to Dsui_0158). All of these genes are conserved in at least one other DPRB, and thus it was unexpected that so many (9 out of 17) had no obvious role in perchlorate reduction (11). However, a similar observation was made in a genetic study of the magnetosome genomic island, where many of the conserved genes were not essential for magnetosome formation (43). Possible reasons proposed for this phenomenon were genetic redundancy, as well as the inherent limitations of laboratory-imposed growth conditions (43). It is reasonable to expect that both of these caveats are relevant for genetic analysis of the PRI.

The perchlorate reductase receives electrons from the electron transport chain via an unknown pathway. PS has a predicted quinol dehydrogenase-type cytochrome c (Dsui_0144) encoded in its PRI that was previously proposed to be a conduit from the quinone pool to the reductase (6), but there was only a slight impairment of growth on perchlorate when the gene was deleted in PS. A similar phenotype was seen with the deletion of the predicted cytochrome b/c gene Dsui_0143. Because none of these genes are absolutely essential for perchlorate reduction, we propose that the electron transport chain to PcrA is redundant. This sort of multiplicity is seen on a larger scale in organisms such as Geobacter spp., which utilize dozens of different cytochrome c proteins to transport electrons across the cell envelope to multiple electron acceptors (44). The perchlorate electron transport chain may not be quite as complex, but additional genetic and biochemical evidence is needed to resolve this pathway in PS. The limitations of our experimental growth conditions may also occlude the phenotypes of certain genes in the PRI. For example, Dsui_0154 and Dsui_0155 are predicted to encode an extracytoplasmic function sigma factor/anti-sigma factor system homologous to SigF and NrsF of Caulobacter crescentus, which has been shown to play a role in activating a response to reactive oxygen species and heavy metal stress (45, 46). The phenotype of these knockouts in PS may be apparent only under the appropriate oxidative stress conditions, which are not met by our standard acceptor-limited conditions in rich medium.

One possible source of oxidative stress associated with perchlorate reduction could be an intermediate of the metabolism. Both the transposon screen and deletion mutagenesis revealed that the cld mutant had a different phenotype from the rest of the perchlorate null mutants when grown on nitrate and perchlorate together (Fig. 3). Interestingly, deletion of pcrA in the Δcld background relieved the growth inhibition (Fig. 4). In the context of perchlorate reduction, chlorite dismutase liberates molecular oxygen from chlorite and sustains the microaerobic respiration that is thought to accompany perchlorate reduction (5). However, Cld can also function to detoxify chlorite, which has been proposed as a role for Cld in organisms that cannot reduce perchlorate or chlorate (47). Chlorite is a powerful oxidant that can result in cell death even at parts-per-million concentrations (48). Previous experiments with PS indicate that perchlorate is not reduced with nitrate in large quantities, but if perchlorate reductase is expressed at all under nitrate-reducing conditions in the absence of Cld, the

FIG 4 Growth characteristics of wild-type PS and the Δcld, ΔpcrA, and Δcld ΔpcrA strains. Growth on nitrate (A), under diauxic conditions (B), or on perchlorate (C) shows that a Δcld ΔpcrA double mutant grows better on mixed electron acceptors than the Δcld and ΔpcrA single mutants.
Micromolar amounts of chlorite that accumulate may result in the inhibition of cell growth. A study performed with cell extracts of the closely related DPRB *Azospira* sp. KJ grown on nitrate showed some perchlorate reductase activity, suggesting that there could be baseline expression of PcrA even under nitrate-reducing conditions (14).

As previously proposed, perchlorate reduction is dependent on genes in the horizontally transferred PRI but also on genes elsewhere in the genome (11). Our transposon screen identified several operons and pathways that are involved in anaerobic respiration. Insertions in hemN (Dsui_1647) and ubiX (Dsui_0993) resulted in pleiotropic mutants that were defective in growth on both nitrate and perchlorate. HemN is an oxygen-independent coproporphyrinogen III oxidase, and UbiX is a decarboxylase involved in the biosynthesis of quinones (49, 50). Presumably, these mutants are deficient in anaerobic heme and quinone biosynthesis, which leads to a general growth defect under anaerobic conditions. Perchlorate reductase requires a molybdopterin-bound molybdenum to function, and several genes involved in molybdopterin biosynthesis were identified in the transposon screen (Table 1). These mutants were also wholly or partially defective during denitrification, which is likely due to the nitrate reductase utilizing the same cofactor. Additionally, the transposon screen allowed the identification of several genes putatively involved in denitrification, which has not been studied directly in PS. These genes include napA, norD, and Dsui_1177. The gene product of Dsui_1177 is a heme-containing protein which has been shown to be upregulated under denitrifying conditions (21). Interestingly, the napA and Dsui_1177 mutants also demonstrate some defects in perchlorate reduction. The reason for this is currently unknown.

Many other genes were identified in the transposon screen as being partially defective in perchlorate reduction and not denitrification, but their specific functions are difficult to predict. These include the *rnf* operon, which was hit by transposons several times in the mutagenesis and screen. The *rnf* operon encodes a membrane-bound redox-active complex which couples the proton (or sodium) gradient of the inner membrane to the cellular redox pools of NAD+/NADH and ferredoxin (51). The activity of the Rnf complex is reversible and has been shown to be important in an array of different bacterial metabolisms, although its role in perchlorate reduction is currently unknown. Other transposon insertions are in genes that are not directly linked to cellular energetics or are in genes that encode hypothetical proteins. Exploring the roles of these genes will be essential to gaining a holistic understanding of perchlorate reduction in the context of global cellular metabolism.

In this article, we set out to address a basic question about the molecular biology of perchlorate reduction: which genes are essential for this metabolism? Transposon mutagenesis and a subsequent screen on medium containing nitrate and perchlorate identified many mutants with insertions in the PRI, accentuating...
its importance. To further characterize this region, we developed a system for making markerless in-frame deletions and systematically knocked out each gene in the PRI. The results of these complementary genetic approaches have increased our understanding of the factors involved in perchlorate reduction (Fig. 5) but have raised many new questions. The histidine kinase system in the PRI is essential for perchlorate reduction, although we know little about how it is activated or which genes it regulates. Specifically, utilization of nitrate over perchlorate is still not understood. The components that deliver electrons to PcrA are also unknown, as is the role played by the nonessential genes in the PRI. Finally, the evolution of the PRI is still obscure; how does the island integrate with the host’s metabolism after it is acquired? Genetic analysis using the deletion and complementation tools developed here will be critical to answering these questions about the evolution and function of the PRI in Azospira salina PS and thus other DPRB.

MATERIALS AND METHODS

Bacterial strains and plasmids. Azospira salina PS (ATCC BAA-33/DSMZ 13638) was revived from a lab freezer stock and used as the wild-type strain for all genetic manipulations (see Table S2 in the supplemental material). Various E. coli strains were also used for cloning and conjugation purposes (see Table S2). Plasmids constructed or used in this study are described in Table S3. Prior to all growth curves and genetic manipulations, all strains were streaked out from master freezer stocks to get single colonies.

Culture conditions and growth media. E. coli strains were grown in LB medium. Kanamycin (50 μg/ml) was used for selection, and dianaminopimelic acid (DAP) (0.3 mM) was used as a supplement to cultivate the auxotrophic strain WM3064. For routine culturing, as well as growth assays, wild-type and mutant strains of PS were grown in ALP medium. One liter of ALP medium is composed of 0.49 g monobasic sodium phosphate dihydrate, 0.97 g dibasic anhydrous sodium phosphate, 0.1 g potassium chloride, 0.25 g ammonium chloride, 0.82 g sodium acetate, 2.0 g yeast extract, 7.6 g of a 60% (wt/wt) sodium lactate solution, 1.10 g sodium pyruvate, and 10 ml of both vitamin mix and mineral mix as previously described (42). To make solid ALP medium for plates, 15 g/liter agar was added. Kanamycin was used for selection of PS mutants at a concentration of 50 μg/ml. For anaerobic growth of PS, ALP medium was supplemented with either 5 mM sodium nitrate, 2.5 mM sodium perchlorate, or 5 mM of both sodium nitrate and sodium perchlorate. No growth was observed when no electron acceptor was added, confirming that PS is unable to grow via fermentation of the carbon sources present in ALP medium. All strains of E. coli and PS were cultivated at 37°C. Anaerobic growth curves of PS for the transposon screen and characterization of strains was performed using a SpectraMax 340PC384 plate reader in an anaerobic chamber (Coy Laboratory Products, Grass Lake, MI).

Transposon mutagenesis via conjugation. The mariner transposon suicide vector pMiniHimar RB1 was used to mutagenize PS (23). WM3064 containing pMiniHimar RB1 (A. Arkin lab, University of California [UC], Berkeley) was grown as over-night culture in 5 ml LB plus Kan plus DAP. This culture was centrifuged and washed twice in ALP medium to remove excess kanamycin. In parallel, a 5-ml culture of PS was grown from a single colony overnight (optical density at 600 nm [OD600] of ~1.5) and centrifuged. The WM3064 and PS cell pellets were resuspended in 50 μl ALP medium and spotted onto an ALP plate supplemented with DAP. The plate was dried by an open flame for 15 min on the benchtop to ensure that the agar surface was dry and the mating reaction did not spread. The plate was then incubated at 37°C for 6 h, after which the entire spot was scraped off the plate and resuspended in 1 ml ALP medium. The volume was divided, plated on 6 ALP-Kan plates, and incubated at 37°C. After 36 to 48 h, ~300 to 500 whitish-pink opaque colonies formed on the 6 plates in total. The colonies were then transferred into 96-well plates containing 300 μl of ALP-Kan medium supplemented with 7.5% glycerol as a cryoprotectant. The plates were then grown overnight aerobically on a platform shaker at 37°C prior to screening and long-term storage at −80°C.

Screening the transposon mutant library. The transposon library was screened prior to long-term storage. From each glycerol freezer stock plate, 10 μl was transferred into 300 μl of ALP-Kan medium supplemented with 5 mM nitrate and perchlorate on the benchtop. Plates were then transferred into the anaerobic chamber, where they were allowed to equilibrate with the anaerobic atmosphere for 1 h. An initial optical density reading was taken, and the plates were placed in a GasPak box (BD) with a palladium catalyst for maintenance of anaerobic conditions. The box was removed from the glove bag and incubated at 37°C. Every 6 to 8 h for 30 h, the box was moved back into the glove bag and the optical density of the plates was measured. The growth curve data were plotted, and mutants that had a defect in either growth rate or maximum optical density were identified. The “mutants of interest” were then streak purified to isolate single colonies on ALP-Kan medium. The single colonies were grown on ALP medium to make long-term freezer stocks.

Characterization of transposon mutants defective in perchlorate reduction. Mutants of interest identified in the initial screen were subjected to further phenotypic characterization. Each mutant was streaked out on ALP-Kan plates from freezer stocks and then transferred into an overnight culture of ALP-Kan liquid medium. The next morning, the optical densities of all strains were determined, and each culture was diluted back to an OD600 of 1.0 to 1.2. A 50-μl aliquot was used to inoculate 1.45 ml of ALP-Kan medium supplemented with either nitrate (5 mM), perchlorate (2.5 mM), or nitrate and perchlorate (both 5 mM). The concentration of perchlorate under the perchlorate-only condition was lowered to avoid unpredictably long lag periods seen with high perchlorate concentrations (unpublished data). Each medium condition was distributed to 4 wells in a 96-well plate such that 8 genotypes could be assayed simultaneously using the SpectraMax plate reader in the anaerobic chamber. The characterization growth curves were allowed to run for 48 h.

Mapping the locations of transposon mutants. Transposon mutants of interest were mapped using a variation of arbitrarily primed PCR methods previously described (52, 53). Briefly, transposon mutants of interest were streaked onto ALP-Kan plates, and single colonies were used as templates for colony PCR. The first round of PCR used a primer that annealed to the end of the mariner transposon (HIMAR_EXT) (see Table S1 in the supplemental material) and one of three arbitrary primers (PS_ARB4, PS_ARB5, and PS_ARB6) which contain a conserved 20-mer at the 5′ end, followed by 10 random nucleotides and one of three most common pentamers in the A. salina PS genome. This first round of PCR used the GoTaq Green master mix (Promega) and the following thermocycling parameters: 10 min at 95°C; 35 cycles of 30 s at 95°C, 30 s at 38°C, and 2 min at 72°C; and 10 min at 72°C. The reaction mixture was treated with ExoSAP-IT (Affymetrix) to remove the primers, and the product was used as the template for a second round of PCR using a transposon primer closer to the genomic insertion site (HIMAR_INT) and a primer consisting of the conserved 20-mer at the 5′ end of the arbitrary primers (PS_ARB2). The second round of PCR used the following thermocycling parameters: 5 min at 95°C; 35 cycles of 30 s at 95°C, 30 s at 55°C, and 2 min at 72°C; and 10 min at 72°C. The second-round PCR product was purified using the QIAquick PCR purification kit (Qiagen) and used as the template for a sequencing reaction with the HIMAR_INT primer (UC Berkeley DNA Sequencing Facility). Sequencing reads were manually curated and used as queries for searching the A. salina genome with BLAST on the NCBI server (54). Sequences were downloaded, and the exact insertion site of the transposon in each mutant was determined.

Constructing suicide vectors and complementation vectors. Genomic DNA from A. salina was isolated using Trizol according to the manufacturer’s directions (Invitrogen), and all PCRs were performed using Phusion DNA polymerase (Fisher Scientific). Specific primer pairs were designed using the NCBI Primer-BLAST server to amplify products
of 800 to 900 bp flanking the gene to be deleted (55). The internal primers closest to the gene were designed to end between codons within the gene so that the resulting deletion would be in-frame and have minimal polar effects on nearby genes. For some genes, the internal primers had a 21-bp “linker” at the 5′ end that was used to assemble the flanking regions into a 1.6- to 1.8-kb insert using PCR. For the remaining genes, the internal primers contained restriction sites that allowed assembly of the suicide vector with a three-way ligation. Both methods used resulted in an in-frame deletion allele of the gene of interest, thereby minimizing polar effects on nearby genes. Sequences and brief descriptions of all primers are listed in Table S1 in the supplemental material.

We used the vector pNPTS138 (Dickson Alley via Kathleen Ryan, UC, Berkeley) as the suicide vector backbone for all of our deletion constructs after testing several plasmids with no success (pAK31, pK19mobsacB, and pSMV3). Deletion vectors were constructed by amplifying two regions flanking the gene of interest and either performing an assembly PCR to fuse the regions together or digesting the PCR product directly. In both cases, the cut vector and digested PCR product(s) was digested with the appropriate restriction enzymes, analyzed by electrophoresis on an agarose gel, and extracted using the Qiagen II gel extraction kit (Qiagen). The broad-host-range plasmid pBRR1MCs2 was used as the backbone for the complementation vectors (56). For three genes (pCRP, pCRS, and pCRR), pBRR1MCs2 and the amplified gene with its promoter were digested, purified, and ligated as described above. For the pcrABCD and cld complementation vectors, the pcrA promoter was first cloned into pBRR1MCs2 to make pRAM62. The amplified genes were then cloned downstream of this promoter as described above to generate these complementation vectors. All ligation reactions were transformed into chemically competent E. coli TOP10 cells and plated on selective medium. Individual colonies were grown overnight in liquid broth, and plasmid DNA was purified, and digested with appropriate restriction enzymes, followed by sequencing of the insert (UC, Berkeley DNA Sequencing Facility).

Electroporation of suicide vectors into PS and screening of deletions. Electropotent A. suillum PS cells were prepared using a method previously described for Zymomonas mobilis (57). One-hundred-microliter aliquots of electropotent cells were thawed on ice and previously described for Electrocompetent cells were grown overnight in liquid broth, and plasmid DNA was purified, and ligated as described above. For the pBBR1MCS2 and the amplified gene with its promoter were digested, purified, and ligated as described above. For the pcrABCD and cld complementation vectors, the pcrA promoter was first cloned into pBRR1MCs2 to make pRAM62. The amplified genes were then cloned downstream of this promoter as described above to generate these complementation vectors. All ligation reactions were transformed into chemically competent E. coli TOP10 cells and plated on selective medium. Individual colonies were grown overnight in liquid broth, and plasmid DNA was purified, and digested with appropriate restriction enzymes, followed by sequencing of the insert (UC, Berkeley DNA Sequencing Facility).

Acknowledgments

Work on (per)chlorate metabolism was supported by funding to J.D.C. from the Energy Biosciences Institute.

We thank Arash Komelli and Kathleen Ryan for gifts of strains and plasmids, as well as valuable advice regarding bacterial genetics and protocol development. We also thank members of the Coates lab, especially Hans Carlson, for critical feedback and discussion regarding this research.
