ABSTRACT

Objective: to evaluate a series of skeletally immature patients who underwent three surgical techniques for anterior cruciate ligament (ACL) reconstruction according to each patient’s growth potential.

Methods: a series of 23 skeletally immature patients who underwent ACL reconstruction surgery at ages ranging from 7 to 15 years was evaluated prospectively. The surgical technique was individualized according to the Tanner sexual maturity score. The surgical techniques used were tranphyseal reconstruction, partial transphyseal reconstruction and extraphyseal reconstruction. Four patients underwent the extraphyseal technique, seven the partial transphyseal technique and twelve the full transphyseal technique, on the ACL. The postoperative evaluation was based on the Lysholm score, clinical analysis on the knee and the presence of angular deformity or dysmetria of the lower limb.

Results: the mean Lysholm score was 96.34 (±2.53). None of the patients presented differences in length and/or clinical or radiographic misalignment abnormality of the lower limbs.

Conclusion: ACL reconstruction using flexor tendon grafts in skeletally immature patients provided satisfactory functional results. Use of individualized surgical techniques according to growth potential did not give rise to physeal lesions capable of causing length discrepancies or misalignments of the lower limbs, even in patients with high growth potential.

Introduction

Anterior cruciate ligament (ACL) injuries in skeletally immature patients are still considered to be infrequent. Although some studies prior to the 1980s stated that ACL injuries in patients with open growth plates were rare findings, some authors of recent studies have reported greater incidence of complete ACL tears in skeletally immature patients, accounting for 0.4% to 3.4% of the lesions.1–5 This increase in the incidence of ACL injuries observed in skeletally immature patients probably results from greater clinical suspicion, improved diagnostic methods and increased participation and demands on children in sports presenting risks of such injuries.

The ideal treatment for ACL tears in skeletally immature patients still remains controversial. Some series that have considered that conservative treatment should be used until the growth plates close have reported unsatisfactory results because the instability continues and secondary lesions develop on the menisci and joint cartilage.5–8 Other authors have also highlighted that this group of patients presents low adherence to the care that is inherent to conservative treatment, particularly with regard to changes in physical activity, the need to use a brace or the frequency of attendance of muscle strengthening programs.9–11

Today, surgical treatment for anterior instability resulting from ACL injury is a promising reality based on evolution of the diagnostic methods and development of new operative techniques.12–18 However, the time and the type of ACL reconstruction surgery to be performed on skeletally immature patients with a high potential for growth remains controversial matters. The presence of growth phases in the distal femur and the proximal tibia is a challenge for ACL reconstruction techniques in immature patients.

The growth cartilage of the distal femur and proximal tibia accounts for most of the lower-limb growth, and for the injuries. In such cases, injuries caused by constructing bone tunnels in ACL reconstruction surgery may result in premature closure of the phase and in consequent unequal lengths and/or angular deformity around the knee.11

The present study had the aim of clinically evaluating a series of skeletally immature patients at different phases of growth who underwent three different ACL reconstruction techniques using autologous grafts from the flexor tendons. The techniques were chosen according to each patient’s growth potential.

Materials and methods

Twenty-three skeletally immature patients who underwent ACL reconstruction surgery to treat complete tears of the ligament were evaluated prospectively. The patients were operated between March 2005 and August 2010. Among the patients included, 19 were male and four were female. The inclusion criterion was the presence of extensively open growth phases at the time of the surgery. The exclusion criteria were a history of previous surgery on the knee involved, failure of the patient to return for clinical evaluations; and refusal to participate, expressed through the patient’s legal representative. This study had previously been approved by the Research Ethics Committee of the University of Passo Fundo.

The patients’ mean age at the time of the surgery was 12.3 years (range: 7–15). Fourteen individuals had been injured on the right knee and nine on the left knee. The mean length of time between the ACL injury and the surgery was 4.8 ± 2.9 months. Twenty individuals (86.9%) suffered ACL injuries by twisting their knee during sports activities: 15 in soccer, three in volleyball, one in handball and one in tennis. Two individuals (8.6%) suffered injuries through falls from bicycles and one (4.3%; the youngest patient) tore the ACL in a fall down the stairs.

The preoperative evaluation was based on the clinical history, preoperative Lysholm score, physical examination, simple X-ray examination and magnetic resonance imaging (MRI) on the knee. In addition to investigation of the trauma mechanism, the clinical history included participation in sports activities before the injury. Anterior instability was evaluated clinically by using the Lachman and pivot shift tests. Each patient’s growth potential was defined at the time of the surgery by using Tanner’s sexual maturity score.19

*EP, extraphyseal reconstruction of the ACL; PTP, partial transphyseal reconstruction of the ACL; TP, total transphyseal reconstruction of the ACL.

**Surgical techniques**

All the patients were positioned in dorsal decubitus under peridural anesthesia or general anesthesia in association with ipsilateral femoral nerve block. A pneumatic tourniquet was used on the proximal third of the thigh. After antisepsis and placement of sterile fields, the lower limb was placed at 45° of hip flexion and 90° of knee flexion. Arthroscopy was performed on the knee by means of anterolateral and anteromedial portals. After confirmation of the diagnosis of tearing of the ACL, the associated injuries to the menisci and cartilage were duly diagnosed and treated. By means of an

---

**Fig. 1 – Protocol for choosing the surgical technique, according to age and Tanner’s sexual maturity score.**
incision of approximately 2 cm in the anteromedial aspect of the proximal tibia, the gracilis and semitendinosus tendons were separated out and removed. Krackow sutures were performed using Ethibond 2-0 thread at the extremity of each tendon graft. The tendon grafts were folded over to form a quadruple graft of at least 10 cm in length. The graft diameter was measured proximally and distally. The remains of the ACL were identified and debrided. From this point onwards, the techniques varied according to the group of patients, as follows.

Transphyseal reconstruction technique (TP)

The centers of the femoral and tibial insertions of the ACL were identified. To construct the femoral tunnel, a guidewire was introduced through the anteromedial portal at the center of the femoral insertion of the ACL. With the knee flexed at 120°, the femoral tunnel was constructed with a length of approximately 20–30 mm and the same diameter as the proximal portion of the graft. The tibial tunnel was constructed by means of a guidewire that was introduced using a tibial guide at an angle of 55°, centered on the tibial insertion of the ACL. The tibial tunnel also presented the same diameter as the graft, measured previously. The graft was then passed through the bone tunnels and was fixed in a post in the femur, by means of a lateral accessory incision; and in the tibia, using a 4.5 mm cortical screw and washer. The tibial fixation was performed with the knee positioned at 30° of flexion (Fig. 2).

Partial transphyseal reconstruction technique (PTP)

In this technique, no femoral tunnel was constructed. The tibial tunnel was constructed in the same way as described in the TP technique. In relation to the femur, the graft was passed around posteriorly to the lateral condyle (over-the-top position), and was fixed on the lateral face of the femur in the same way as described previously (Figs. 3 and 4).

Extraphyseal reconstruction technique (EP)

In this technique too, no femoral tunnel was constructed. The tibial tunnel was constructed by means of a guidewire that was introduced above the proximal phase of the tibia, with the aid of fluoroscopy, and was directed to the center of the tibial insertion of the ACL (Fig. 5). The diameter of the tibial tunnel was the same as that of the graft. The graft was passed around posteriorly to the lateral condyle (over-the-top position) and was fixed using the same technique as described previously (Figs. 6 and 7).

Results

After a mean follow-up of 35.4 ± 15.3 months, the mean score from the Lysholm functional evaluation was 96.3 ± 2.5 (Table 2). All the patients presented a hard stop in the Lachman test and only two (8.6%), who were both in the TP group, presented a +/4 result in the pivot test (patients 14 and 20). However, neither of these patients presented any complaint of clinical instability of the knee. Nineteen patients (82.6%) returned to their pre-injury physical activity levels and four (17.4%) reported that they had not returned to sports practice at the same level as before the injury, even though the knee was considered stable according to the clinical criteria and functional score. None of the patients presented dysmetria of the lower limbs greater than 10 mm. No clinical or radiographic sign of misalignment in the coronal and/or sagittal planes was observed.

Regarding complications, one patient presented a superficial hematoma in the donor area of the flexor tendons. One patient reported medial pain in the thigh two years after the operation, caused by proximal migration of the bicortical screw that had been used for femoral fixation (patient 1). In this case, the patient underwent surgery to remove the
implant, which led to complete remission of the symptoms. Furthermore, one of the patients who underwent meniscal suturing presented recurrence of the lesion in the posterior cornu of the medial meniscus two years after the operation, and was then treated with partial meniscectomy of the medial meniscus (patient 13).

Discussion

Even with increasing numbers of cases, ACL injuries in skeletally immature patients are still considered to be uncommon.20 This low incidence has meant that there is no consensus regarding its management, particularly in dealing with patients with a high potential for growth.

It is important to emphasize that although choosing conservative treatment eliminates the iatrogenic possibilities of surgery, the results obtained are generally unsatisfactory.2,5,23 Kannus and Jarvinen23 evaluated 33 patients with ACL tears that were treated conservatively and most of these patients presented unsatisfactory results because of the recurrent instability. One third of the patients already showed degenerative alterations on radiological examinations at the end of the follow-up.

Surgical treatment of ACL injuries in patients with the open phase requires special attention because of the possibility of iatrogenic injury to the growth plate during construction of the bone tunnels. It is important to emphasize that each patient’s potential for growth, which is assessed from the physiological skeletal maturity, may have a standard deviation of around one year for each chronological age.24 Skeletal maturity should be assessed before the surgery, and the risk of damage to the growth cartilage should be gauged. It is known that approximately 65% of the growth of the lower limb occurs around the knee,25 and perforation of the physis may cause localized epiphysiodesis and leads to growth discrepancy (complete epiphysiodesis) or angular deformity (partial epiphysiodesis). In a study using magnetic resonance imaging, Sasaki et al.26 showed that the growth physis around the knee did not show any sign of closure in patients under the age of 11 years. Only 34% of the physis of the knee were closed at the age of 13 years, and the physis were only completely closed over the age of 16 years. In this same study, the authors also emphasized that closure of the physis took place from the central portion toward the peripheral portion.

The ideal time for surgical intervention, and also the choice of technique to minimize the damage to the growth cartilage, is an important factor in the planning. Some authors have

Fig. 4 – Anteroposterior (A) and lateral (B) X-rays on a 12-year-old patient with Tanner 3 who underwent ACL reconstruction using the PTP technique. Note the verticalized and centralised tibial tunnel.

Fig. 5 – Fluoroscopy showing the position of the guidewire for the extraphyseal (EP) tibial tunnel.
recommended that the reconstruction should be done closer to the time of skeletal maturity, in order to diminish the risk of damage to the growth cartilage.\textsuperscript{10,19,27} Woods et al.\textsuperscript{27} observed that there were 20\% more meniscal injuries in patients whose surgery was postponed for more than six months, in comparison with a group that underwent earlier reconstruction with restrictions on activities. Millet et al.\textsuperscript{10} showed that there was an association between medial meniscal injury and the length of time from the injury to the reconstruction. McIntosh et al.\textsuperscript{28} did not observe any development of new meniscal injuries after ACL reconstruction, which justified their decision to perform early surgical intervention. In the present study, 12 patients presented meniscal injury at the time of the surgery, which may have been related to greater chronicity among our cases.

Use of a graft composed only of soft tissues, without any presence of bone material, is another factor that contributes toward diminishing the risk of disturbances during the growth phase.\textsuperscript{17,19,29} McIntosh et al.\textsuperscript{28} obtained satisfactory results by using grafts from autologous flexor tendons, with only one case of discrepancy of length in the lower limbs.

In a systematic review, Vavken et al.\textsuperscript{30} evaluated 47 studies relating to top conservative and surgical treatment of ACL injuries in skeletally immature patients. The conservative treatment was correlated with unsatisfactory clinical results and with high incidence of secondary meniscal and cartilage lesions. A few studies have correlated surgical treatment with growth disorders and have shown strong evidence that surgical treatment is correlated with good functional results and joint stability. In those authors’ evaluation, no specific surgical technique was shown to be superior. Among the studies evaluated, only nine included patients who underwent techniques that preserved the growth cartilage. Thirty-one studies reported results from patients after ACL reconstruction with at least one transphyseal tunnel. In this group of

Fig. 6 – Illustration demonstrating the extraphyseal technique (EP).
approximately 500 patients of mean age 13.6 ± 0.9 years, in whom at least one of the tunnels was constructed during the growth phase, only three patients presented angular deformities and two showed growth disorders. Thus, the authors of the systematic review concluded that there was no significant difference in the results between patients with one and two transphyseal tunnels, and they considered the transphyseal technique to be safe.

Despite the evidence presented in the study by Vavken et al., it has to be taken into consideration that the great majority of the published studies included presented evidence level IV and that, moreover, the patients’ mean age was approximately 13 years. There was only one study with evidence level II in this review. Few authors have solely evaluated patients with a high potential for growth (Tanner I and II). Liddle et al. and Streich et al. reported good clinical results using transphyseal techniques in patients with a high potential for growth, but the small number of patients in each series and the type of study design were limiting factors. In a recent retrospective study on 16 skeletally immature patients with high potential for growth (Tanner 1 and 2), Hui et al. evaluated the results from arthroscopic anatomical reconstruction using soft-tissue grafts. In this series, the authors did not find any alignment and growth disorders over a mean follow-up period of 25 months. All of the patients returned to their pre-injury activity levels.

In a recent systematic review, Moksnes et al. emphasized the low quality of the studies available, according to the Coleman methodology score. Out of the 31 studies included in this review, only two were prospective and no randomized clinical trials on this subject were found. In these authors’ opinion, greater attention needs to be given to study design and sample size. There is a need for prospective observational studies to assess late and rare events.

In the study presented here, we considered that there was no strong scientific evidence that transphyseal ACL reconstruction techniques were completely safe in patients with high potential for growth. Thus, the surgical techniques were individualized according to each patient’s potential for growth. Individuals with high potential for growth should still be operated on, but using techniques that present lower risk of damage to the growth cartilage.

Like most other studies involving treatment of ACL injuries in skeletally immature patients, this study presented some limitations: it was a case series with a relatively short follow-up and also involved a small number of patients. However, this is the first study in the Brazilian literature to describe different technical options among patients with different potentials for growth. We chose not to conduct a case-control study because of the current evidence that contraindicates conservative treatment among these patients and the lack of strong evidence to show that transphyseal reconstruction would be safe for patients with a high potential for growth.

Conclusion

ACL reconstruction using grafts from flexor tendons in skeletally immature patients produced satisfactory functional results. Use of techniques individualized according to the potential for growth, use of grafts composed only of soft tissue and fixation away from the physis are important factors to be born in mind in surgical management of ACL injuries in patients with a high potential for growth.
