(Dated: March 22, 2022)

Bloch waves and Bloch band of Bose-Einstein Condensates in optical lattices are studied. We provide further evidence for the loop structure in the Bloch band, and compute the critical values of the mean-field interaction strength for the Landau instability and the dynamical instability.

I. INTRODUCTION

Bose-Einstein condensates (BECs) in optical lattices have been attracting increasing attention from both theorists and experimentalists. People are interested in how the interaction and coherence of this system affect the interesting phenomena observed with dilute cold atoms in optical lattices, such as Landau-Zener tunneling and Bloch oscillations. Recent studies have shown that these phenomena are indeed strongly influenced by the interaction between atoms. A series of novel effects have been discovered, including the nonlinear Landau-Zener tunneling, the breakdown of Bloch oscillations, and dynamical instability. There are similar nonlinear periodic systems in other fields, for example, the system of the nonlinear guided waves in a periodic layered medium.

In a one dimensional optical lattice created by two counter-propagating off-resonance laser beams, a BEC is essentially a one dimensional system when the lateral motion can be either neglected or confined. Its grand canonical Hamiltonian is

$$H = \int_{-\infty}^{\infty} dx \left\{ \psi^* \left( -\frac{1}{2} \frac{\partial^2}{\partial x^2} + v \cos x \right) \psi + \frac{c}{2} |\psi|^4 - \mu |\psi|^2 \right\},$$

where $\psi$ is the macroscopic wave function of the BEC. In the above equation, all the variables are scaled to be dimensionless with the system’s basic parameters, the atomic mass $m$, the wave number $k_L$ of the two laser lights, and the average density $n_0$ of the BEC. The strength of the periodic potential $v$ is in units of $\frac{\hbar^2 k^2}{2 m}$, the wave function $\psi$ in units of $\sqrt{n_0}$, $x$ in units of $\frac{1}{2 k_L}$, and $t$ in units of $\frac{m}{2 \hbar k_L}$. The coupling constant $c = a_s \frac{1}{n_0 k_L^2}$, where $a_s > 0$ is the s-wave scattering length. A two dimensional version of this system has also received some attention.

In this Brief Report, we study the Bloch bands and Bloch waves of a BEC in an optical lattice, and present new results that we were unable to obtain in our previous studies. These new results are possible now due primarily to a new development, an exact solution found in Ref. 4. As Bloch bands and Bloch waves are the two most important concepts in understanding a linear periodic system, they shall also play crucial roles in the physics of the nonlinear periodic system of the form

$$\psi(x,t) = e^{ikx} \phi_k(x),$$

where $\phi_k(x)$ is a periodic function of period $2\pi$ and $k$ is the Bloch wave number. Each Bloch wave state satisfies the time-independent Gross-Pitaevskii equation

$$-\frac{1}{2} \frac{\partial^2}{\partial x^2} + v \cos x \phi_k + c |\phi_k|^2 \phi_k = \mu \phi_k,$$

as can be verified by variation of the Hamiltonian of the form

II. BLOCH BANDS

In Ref. 1, we studied the tunneling between the two lowest bands to see how it is affected by the interaction. We found that the tunneling is described by a revised Landau-Zener model, which we call the nonlinear
Landau-Zener model. This model predicts a dramatic change in the band structure, which is a loop appearing at the Brillouin zone edge \( k = \pm 1/2 \) for \( c/v > 1 \) (see Fig. 1). A direct consequence of this loop structure is the breakdown of the Bloch oscillations due to the non-zero adiabatic tunneling into the upper band.

The loop structure is confirmed by an exact solution found recently by Bronski et al. (Eq.(10) of Ref.[4]), which assumes a much simpler form in terms of our notations,

\[
\psi_B(x) = a_+ e^{i \frac{x}{c}} + a_- e^{-i \frac{x}{c}},
\]

where \( a_\pm = \sqrt{\frac{\sqrt{1 + 4 c^2/v^2} - 1}{2 \sqrt{c/v}}} \). Substituting it into Eq.(3), we have \( \mu = \frac{1}{2} + c \). This solution only exists when \( c \geq v \), and is a Bloch wave at the edge of the Brillouin zone, \( k = 1/2 \). This Bloch wave carries a non-zero velocity, \( \sqrt{\frac{v^2 - c^2}{2c}} \), while its complex conjugate has an opposite velocity. This is in sharp contrast with the behavior in a linear periodic system, in which Bloch waves at the zone edge always have zero velocity. This difference confirms the looped band structure. The solution \( \psi_B \) and its complex conjugate are the two degenerate states at the crossing point \( X \) (Fig. 1). The non-zero velocity carried by this Bloch wave is a manifestation of superfluidity of BEC. For free particles, the flow \( e^{ix/2} \) is stopped completely by Bragg scattering from the periodic potential; for the BEC, the flow can no longer be stopped when the superfluidity is strong, that is, \( c > v \).

This loop structure is further supported by our numerical calculation of the lowest band \( \mu(k) \), as shown in Fig. 1. It is evident that the slope \( d\mu/dk \) at the zone edge \( k = \pm 1/2 \) becomes non-zero as the interaction strength \( c \) is increased over the periodic potential strength \( v \), a clear indication of the loop structure. However, due to the limitation of our numerical method [2], we are unable to produce directly the loop. An improved numerical method is being developed to calculate the loop and the higher Bloch bands.

### III. STABILITY OF BLOCH WAVES

In our second paper [3], we studied the superfluidity and stability of the Bloch waves in the lowest band (excluding the loop). We found that the Bloch waves in the middle of the Brillouin zone represent super-flows, and the other Bloch waves towards the zone edge have both a Landau instability and a dynamical instability. Moreover, we found that these instabilities can disappear from all these Bloch waves when the atomic interaction is beyond certain critical values for a fixed lattice strength. For easy reference, we call the critical value for the Landau instability \( c_L \), and the critical value for the dynamical instability \( c_d \). In that work, we were unable to find these two critical values because our numerical method was not good enough to find accurate Bloch waves at the zone edge. Now the exact solution \( \psi_B \) allows us to overcome the difficulty and calculate these two critical values, \( c_L \) and \( c_d \). It is done by studying the stabilities of the Bloch wave \( \psi_B \). Since the Bloch wave at the zone edge is the last one to become stable either in terms of the Landau instability or dynamically, the critical values of \( c \) for \( \psi_B \) to become stable are just \( c_L \) and \( c_d \).

The physical significance of the two critical values, \( c_L \) and \( c_d \), lies in the way how the Bloch states at \( k \neq 0 \) are achieved experimentally: the Bloch state at \( k = 0 \) is first prepared then driven to the desired Bloch states at \( k \neq 0 \) by accelerating the optical lattice [10]. Therefore, as the only point connecting the loop to the rest of the Bloch band, a stable \( \psi_B \) means that the Bloch states on the loop can be accessed and studied experimentally by accelerating the optical lattice.

We first study the Landau instability by analyzing how the energy of the system deviates under a small perturbation. Since the system is periodic, we are allowed to write the perturbation as

\[
\psi = \psi_B + e^{ix} (u(x,q)e^{iqx} + v^*(x,q)e^{-iqx}),
\]

where \( q \) ranges between \(-1/2 \) and \( 1/2 \), labelling the perturbation mode, and the perturbation functions \( u \) and \( v \) have a periodicity of \( 2\pi \) in \( x \). Then the energy deviation caused by this perturbation is

\[
\delta E = \int_{-\infty}^{\infty} dx \left( u^* \frac{\partial}{\partial x} u + v^* \frac{\partial}{\partial x} v \right) M(q) \begin{pmatrix} u \\ v \end{pmatrix},
\]

where

\[
M(q) = \begin{pmatrix} L(1/2 + q) & c \phi_B^2 \\ c \phi_B^2 & L(-1/2 + q) \end{pmatrix},
\]

with

\[
L(k) = -\frac{1}{2} \left( \frac{\partial}{\partial x} + ik \right)^2 - v \cos x + c - \frac{1}{8}
\]
and

$$\psi_B^2 = \frac{c + \sqrt{c^2 - v^2}}{2c} - \frac{v}{c} e^{-ix} + \frac{c - \sqrt{c^2 - v^2}}{2c} e^{-2ix}. \quad (9)$$

If $M(q)$ is positive definite for all $-1/2 \leq q \leq 1/2$, the Bloch wave $\psi_B$ is a local minimum and a super-flow. Otherwise, $\delta E$ can be negative for some $q$; the Bloch wave is a saddle point and has a Landau instability. As already noticed in Ref. [2], the positive definiteness of the matrices $M(q)$ for all $q$‘s is guaranteed by the positive definiteness of $M(0)$. Diagonalizing $M(0)$ for different values of $c$ with a fixed $v$, we obtain the critical value $c_L$, which is shown as a dashed line in Fig. 3. For the intersection point $L$ at $v = 0$, we have $c_L = 1/4 = (k = 1/2)^2$.

**FIG. 3:** The critical values of $c$. The dashed line is $c_L$, the critical value of $c$ for all the Bloch waves in the lowest band being super-flows; the solid line is $c_d$, above which all the Bloch waves in the lowest band are dynamically stable.

The dynamical stability of the Bloch wave $\psi_B$ is studied by linearizing the Gross-Pitaevskii equation

$$i \frac{\partial \psi}{\partial t} = \frac{-1}{2} \frac{\partial^2 \psi}{\partial x^2} + c|\psi|^2 \psi + v \cos x \psi. \quad (10)$$

With a procedure similar to the above, we arrive at the linearized dynamical equation

$$i \frac{\partial}{\partial t} \begin{pmatrix} u \\ v \end{pmatrix} = \sigma M(q) \begin{pmatrix} u \\ v \end{pmatrix}, \quad \sigma = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}. \quad (11)$$

The dynamical stability is determined by the matrix $\sigma M(q)$. If all $\sigma M(q)$ for $-1/2 \leq q \leq 1/2$ have no complex eigenvalues, then $\psi_B$ is dynamically stable; otherwise, it is unstable. However, as pointed out in Ref. [3], the dynamical instability always starts at the perturbation mode $q = 1/2$. Therefore, we only need to diagonalize $\sigma M(1/2)$ to find the critical value $c_d$. The results are shown as the solid line in Fig. 3, where the intersection $D$ at $v = 0$ is precisely $c_d = 3/16$. This lower bound of the critical value $c_d$ simply means that when $c < 3/16$, any periodic potential brings the dynamical instability into the system.

The value of $c_d$ at point $D$ is confirmed by analyzing the limiting case $v \ll c$, where the matrix $\sigma M(1/2)$ can be approximated with a $4 \times 4$ matrix

$$\sigma M(1/2) \approx \begin{pmatrix} c - \frac{1}{8} & 0 & c & -v \\ 0 & c + \frac{3}{8} & 0 & c \\ -c & 0 & -\frac{3}{8} - c & 0 \\ v & -c & 0 & \frac{1}{8} - c \end{pmatrix}. \quad (12)$$

The eigenvalues of this matrix can be found exactly; all of them are real only when $c > 3/16$. Note that the point $D$ must be understood in a sense that $c_d \rightarrow 3/16$ as $v \rightarrow 0$ since precisely at $v = 0$ the system has no dynamical instability. As one may get an impression from Fig. 3, that the asymptotic behavior of the two curves at large $v$ is linear, we want to stress that it is not. Our numerical results show that the asymptotic behavior undergoes very small oscillations along a straight line, which we have no complete understanding.

Besides the existence of the loop structure shown in Fig. 3, we have not discussed the properties of the states on the loop due to the difficulty finding these loop states accurately. Here we offer a glimpse of these loop states and their properties. Around the crossing point $X$ (Fig. 3) $k = 1/2 + \epsilon (|\epsilon| \ll 1)$, the Bloch wave can be approximated to the zeroth order of $\epsilon$ as

$$\psi(x) = \frac{\sqrt{h} + 1 + \sqrt{h - 1} e^{ikx}}{2\sqrt{h}} - \frac{\sqrt{h} + 1 - \sqrt{h - 1}}{2\sqrt{h}} e^{i(k-1)x}, \quad (13)$$

where $h = \frac{c}{v} + \frac{1}{2} \epsilon$. Numerical investigations show that most of these loop states are all saddle points which can be either dynamically stable or unstable. More numerical calculations are needed to further confirm this.

Finally, we make two remarks. First, the way of defining Bloch waves and Bloch bands for the nonlinear system (4) at the beginning is a natural generalization from the linear periodic system. Nevertheless, there is an essential difference due to the nonlinearity. In the linear system ($c = 0$), the Bloch waves are the only extremum states of its Hamiltonian or the only eigenfunctions of Eq. (3); for the nonlinear system (4), there are possible extremum states that are not Bloch waves.

Second, it is interesting to put the dynamical instability which is discussed in this report and in Ref. [2, 4, 5] into perspective. Usually, a quantum dynamics is a regular motion because it has discrete eigenvalues thus an almost periodic motion no matter its corresponding classical dynamics is chaotic or not. In this sense, quantum chaos has been called “pseudochaos” [13]. On contrary, the dynamical instability that we have discussed is “true” quantum dynamical chaos that deserves more attention in the future.

On the other hand, with the Madelung transformation $\psi(x,t) = \rho(x,t) e^{i\mathcal{S}(x,t)}$, the nonlinear Schrödinger equation (11) can be turned into a set of equations of fluid
dynamics. In this regard, the quantum dynamical instability should be related to the turbulence in the fluid dynamics, and we may call it “quantum turbulence”.
