Abstract We investigate the following questions: Given a measure $\mu_\Lambda$ on configurations on a subset $\Lambda$ of a lattice $L$, where a configuration is an element of $\Omega^\Lambda$ for some fixed set $\Omega$, does there exist a measure $\mu$ on configurations on all of $L$, invariant under some specified symmetry group of $L$, such that $\mu_\Lambda$ is its marginal on configurations on $\Lambda$? When the answer is yes, what are the properties, e.g., the entropies, of such measures? Our primary focus is the case in which $L = \mathbb{Z}^d$ and the symmetries are the translations. For the case in which $\Lambda$ is an interval in $\mathbb{Z}$ we give a simple necessary and sufficient condition, local translation invariance (LTI), for extendibility. For LTI measures we construct extensions having maximal entropy, which we show are Gibbs measures; this construction extends to the case in which $L$ is the Bethe lattice. On $\mathbb{Z}$ we also consider extensions supported on periodic configurations, which are analyzed using de Bruijn graphs and which include the extensions with minimal entropy. When $\Lambda \subset \mathbb{Z}$ is not an interval, or when $\Lambda \subset \mathbb{Z}^d$ with $d > 1$, the LTI condition is necessary but not sufficient for extendibility. For $\mathbb{Z}^d$ with $d > 1$, extendibility is in some sense undecidable.

Keywords Local translation invariance · Translation invariant extensions · Maximal entropy extensions · de Bruijn graphs · Bethe lattice

Dedicated to David Ruelle and Yasha Sinai on the occasion of their eightieth birthdays.

1 Introduction

We consider an extension problem for measures describing configurations on a lattice $\mathbb{L}$, in which the value $\eta_i$ of the configuration $\eta$ at site (or equivalently vertex) $i$ of $\mathbb{L}$ belongs to some fixed set $\Omega$. Let $X = \Omega^\mathbb{L}$ be the set of all configurations on $\mathbb{L}$, and, for $\Lambda \subset \mathbb{L}$, let $X_\Lambda = \Omega^\Lambda$ be the set of configurations on $\Lambda$. Then we address the following extension problem: for a fixed $\Lambda \subset \mathbb{L}$ and probability measure $\mu_\Lambda$ on $X_\Lambda$, does there exist a probability measure $\mu$ on $X$ such that (i) $\mu$ is invariant under some specified group of symmetries of $\mathbb{L}$ and (ii) the marginal measure of $\mu$ on $X_\Lambda$ is $\mu_\Lambda$? When $\mu$ exists we speak of it as an invariant extension of $\mu_\Lambda$ or, since we consider only invariant extensions, simply as an extension. In this case we say that $\mu_\Lambda$ is extendible.

For most of this paper the lattice $\mathbb{L}$ will be taken to be $\mathbb{Z}^d$ for some $d \geq 1$, and the symmetries of interest will be translations or, occasionally, translations plus reflections about a coordinate axis. In this case we will refer to an invariant extension $\mu$ as a TI extension or, as above, simply as an extension. In Sect. 3 we discuss the case in which $\mathbb{L}$ is the Bethe lattice.

Schlijper [27–30] studied the problem of TI extensions on $\mathbb{Z}^d$ in the 1980’s, in connection with its application to the cluster-variation method [22], used to obtain approximations to the equilibrium thermodynamic properties of lattice systems. The problem was also studied by Pivato [24] in 2001 and by Chazottes et al. [6] in 2012. For completeness we will summarize or rederive some of the results of these papers in the course of describing our own work; we discuss this in more detail at the end of this section.

For $\Lambda \subset \mathbb{Z}^d$ we say that measure $\mu_\Lambda$ on $X_\Lambda$ is locally translation invariant (LTI) if for any subsets $A$, $A' \subset \Lambda$, with $A'$ a translate of $A$, the marginal of $\mu_\Lambda$ on $X_{A'}$ is the translate of the marginal on $X_A$. The LTI property is clearly necessary for the existence of a TI extension $\mu$ of $\mu_\Lambda$ and one question we investigate is whether or not it is also sufficient.

From now on we will assume that, unless otherwise stated, $\Lambda$ is finite. Our primary focus will be the case in which $\Omega$ is finite. Our results then do not depend significantly on the cardinality of $\Omega$; for simplicity of presentation we will often take $\Omega$ to be $\{0, 1\}$, so that a configuration $\eta \in X$ may be thought of as describing a particle system or point process on the lattice. We will occasionally point out instances in which our results extend to certain infinite $\Omega$.

For finite $\Omega$ we have a good understanding of the situation when $d = 1$ and $\Lambda$ is an interval. In particular, the LTI condition is in this case sufficient for the existence of the TI extension [24,29], as we verify in Sect. 2 by an explicit construction of such an extension; the resulting $\mu$ is in fact the unique TI extension which maximizes the entropy of its marginal on $X_{\Lambda'}$ for any interval $\Lambda' \supset \Lambda$. Moreover, if $\Lambda$ contains $k + 1$ sites then $\mu$ is the shift-invariant measure on the sample paths of a $k$-step Markov process, and as such is a Gibbs measure with TI interactions which have range at most $k$ and involve at most $k + 1$ sites. We obtain an explicit expression for the Gibbs–Shannon entropy of $\mu_{\Lambda'}$ as an affine function of the size of $\Lambda'$. This extension method applies also when $\Lambda$ is an infinite strip in $\mathbb{Z}^2$ or a higher-dimensional analogue of such a strip, or is one of a certain class of subgraphs of the Bethe lattice which are analogous to intervals in $\mathbb{Z}$.

In the one-dimensional case, with $\Lambda$ an interval, $\Omega$ finite, and $\mu_\Lambda$ LTI, there exist also TI extensions of $\mu_\Lambda$ which are supported on a finite number of periodic configurations [6]. We discuss this and related results in Sects. 4 and 5. Every TI measure of this type has finite entropy, in a sense which will be made precise later, and we show that every extension with minimal entropy is of this type (there is in general no unique minimal entropy extension). However, for general $\mu_\Lambda$ we are not able to give an explicit construction of a minimal entropy
extension or even to determine the minimal entropy, although we do give an a priori bound for the latter. A key element of our analysis here is the identification of a measure on $X_\Lambda$ with an edge-weighting of a de Bruijn graph; the LTI condition on the measure then corresponds to current conservation at the vertices of the graph.

When one passes to the extension problem for $\Lambda$ not an interval of $\mathbb{Z}$ the situation is more complex. In Sect. 6 we give simple examples of LTI measures $\mu_\Lambda$ which are not extendible; for example, with $\Lambda = \{i, i + 1, i + 3\} \subset \mathbb{Z}$ and $\Lambda$ a unit square in $\mathbb{Z}^2$ (with four lattice sites). For the latter example it is relevant to remark that when $\Lambda \subset \mathbb{Z}^2$ is a product of intervals, and $\mu_\Lambda$ is LTI, the maximal entropy extension procedure mentioned above can be used to extend $\mu_\Lambda$ in one direction, i.e., to an infinite strip, and the resulting extension is TI in the direction of extension. In this process, however, the LTI property in the second direction may be lost; only if it is preserved can one repeat the process to obtain an extension to all of $\mathbb{Z}^2$. Similar remarks apply in higher dimensions.

As noted above, when $\Omega = \{0, 1\}$ we are studying point processes on $\mathbb{Z}^d$. In this context the current paper may be viewed as continuing work on a long-standing problem: the existence of point processes when one is given partial information about the desired process (see, for example [8, 23, 31] and further references given in [17]). In our own previous work [4, 7, 16, 17] we considered the case in which the information given was all $k$-point correlation functions of the process up to some order $k_0$; this is in essence a truncated moment problem. Extending the work of [1] we obtained a sufficient condition, essentially one of low density, for the existence of the process. Complete necessary and sufficient conditions were found in [17]; these are worked out in detail for the case $k_0 = 2$, but the method is general. See also [18].

We finally note that, for fixed $\Lambda \subset \mathbb{Z}^d$, the set of measures $\mu_\Lambda$ on $X_\Lambda$ which can be extended to a TI measure on $\mathbb{Z}^d$ is closed in the weak topology. For if $(\mu_\Lambda, n)_{n=1}^\infty$ is a sequence of measures on $X_\Lambda$ converging weakly to a measure $\mu_\Lambda$, and $\tilde{\mu}_n$ is a TI extension of $\mu_{\Lambda, n}$ to $X$, then some subsequence of $(\tilde{\mu}_n)_{n=1}^\infty$ will converge, by compactness, and the limit will be a TI extension of $\mu_\Lambda$.

The outline of the rest of the paper is as follows. In Sect. 2 we show that the LTI condition is sufficient, when $\Lambda$ is an interval in $\mathbb{Z}$, for the existence of a TI extension; we do so by explicit construction of the maximal entropy, Markovian, extension. We also point out that this extension is Gibbsian. In Sect. 3 we take up the extension problem on the Bethe lattice; there also we construct maximal entropy extensions which are Markovian and Gibbsian. In Sect. 4 we return the the case in which $\Lambda$ is an interval in $\mathbb{Z}$ and discuss a different class of extensions, those supported on periodic configurations, and in Sect. 5 show that these include the extensions of minimal possible entropy. In Sect. 6 we give several examples to show that, in $\mathbb{Z}^d$, the LTI condition is not sufficient for extendibility when $\Lambda$ is not an interval in $\mathbb{Z}$; we give also a corresponding example for the Bethe lattice. Section 7 takes up the issue of the decidability of the extension problem.

We finally discuss briefly the overlap of this paper with other work. As noted above, the Markovian extension of Sects. 2 and 2.1 has been discussed before, see in particular [24, 29], although its Gibbsian nature has not been noted. Periodic extensions are discussed [6, 24], and our results in Sect. 4 partially overlap with this work. Our discussion of the Bethe lattice in Sect. 3 is, we believe, new, as is the discussion of minimal entropy measures in Sect. 5. Examples 16 and 17 of Sect. 6 are new. We first learned of the existence of undecidability questions for the extension problem in higher dimensions from Ruelle [26]; aspects of this problem have also been discussed in [6, 24, 30], but we give a formulation that we feel has something new to offer.
2 Maximal Entropy Extensions in One Dimension

We will adapt the general notation of the introduction to the one-dimensional case considered in this and in Sects. 4 and 5 by letting $\Lambda_k$, for $k \geq 0$, be the subset $\{0, 1, \ldots, k\}$ of $\mathbb{Z}$, $X_k = \{0, 1\}^{\Lambda_k}$ be the set of particle configurations on $\Lambda_k$, and $\pi_k \mu$, for $\mu$ a measure on $X$ or on $X_j$ with $j > k$, be the marginal of $\mu$ on $X_k$. We suppose that we are given an LTI measure $\mu_k$ on $X_k$ and construct explicitly a (TI) measure $\mu$ on $X = \{0, 1\}^\mathbb{Z}$ which extends $\mu_k$, i.e., satisfies $\pi_k \mu = \mu_k$.

We will usually invoke the condition that $\mu_k$ is LTI as the requirement that the marginal $\mu_{k-1} = \pi_{k-1} \mu_k$ of $\mu_k$ on $X_{k-1}$ be the translation of the marginal on configurations on the sites $\{1, 2, \ldots, k\}$:

\[
\mu_{k-1}(\eta_0, \ldots, \eta_{k-1}) = \sum_{\sigma=0,1} \mu_k(\eta_0, \ldots, \eta_{k-1}, \sigma),
\]

\[
= \sum_{\sigma=0,1} \mu_k(\sigma, \eta_0, \ldots, \eta_{k-1}) \tag{1}
\]

We say that $\mu_k$ is symmetric if it is invariant under reflections about the center of $\Lambda_k$. It is easy to verify that if $\mu_k$ is LTI and $j < k$ then the marginal of $\mu_k$ on $X_j$ is also LTI, and if $\mu_k$ is also symmetric then so is this marginal. In fact, a symmetric measure $\mu_k$ is LTI if and only if its marginal on $X_{k-1}$ is symmetric.

We begin the construction of $\mu$ by extending $\mu_k$ to an LTI measure $\mu_{k+1}$ on $X_{k+1}$, defining $\mu_{k+1}(\eta_0, \eta_1, \ldots, \eta_{k+1}) = 0$ if $\mu_{k-1}(\eta_1, \ldots, \eta_k) = 0$, and

\[
\mu_{k+1}(\eta_0, \eta_1, \ldots, \eta_{k+1}) = \frac{\mu_k(\eta_0, 1, \ldots, \eta_k) \mu_k(\eta_1, 2, \ldots, \eta_{k+1})}{\mu_{k-1}(\eta_1, \ldots, \eta_k)}, \tag{2}
\]

otherwise. One verifies easily that $\mu_{k+1}$ is LTI and has marginal $\mu_k$ on $X_k$. Moreover, if $\mu_k$ is symmetric, so is $\mu_{k+1}$. This leads immediately to the main result of this section.

**Theorem 1** If $\mu_k$ is an LTI measure on $X_k$ then there exists a TI measure $\mu$ on $X$ which extends $\mu_k$. Moreover, if $\mu_k$ is symmetric then $\mu$ may be taken to be symmetric under any reflection.

**Proof** Suppose $\Lambda = \{-l, -l + 1, \ldots, j\}$ with $l \geq 0$ and $j \geq k$. By the repeated application of (2) (and a translation) one may find, for any $l$ and $j$, an LTI measure $\mu_{\Lambda}$ on $\{0, 1\}^\Lambda$ whose marginal on $X_k$ is $\mu_k$. The result then follows from the Kolmogorov existence theorem. The preservation of symmetry is immediate. \(\square\)

There is another approach to this extension procedure. Equation (2) can be written as

\[
\mu_{k+1}(\eta_0, \eta_1, \ldots, \eta_{k+1}) = \mu_k(\eta_0, \eta_1, \ldots, \eta_k) \mu_k(\eta_{k+1} | \eta_1, \ldots, \eta_k), \tag{3}
\]

where the conditional probability $\mu_k(\xi_k | \xi_0, \ldots, \xi_{k-1})$ is defined to be zero whenever $\mu_{k-1}(\xi_0, \ldots, \xi_{k-1}) = 0$, and then one sees that the extension procedure described in the proof of Theorem 1 is equivalent to

\[
\mu_j(\eta_0, \eta_1, \ldots, \eta_j) = \mu_k(\eta_0, \ldots, \eta_k) \prod_{i=1}^{j-k} \mu_k(\eta_{i+k} | \eta_i, \ldots, \eta_{i+k-1}). \tag{4}
\]

Equation (4) says that we may regard the extension procedure as defining a Markov chain with state space $\{0, 1\}$ having memory, for which the transition probabilities depend on states.
The extension method in the Markovian form (4) is well defined for a large class of
invariant measures on sample paths for this chain. Equivalently one may think of a 1-step
Markov chain with state space $X_k$.

**Remark 2** It is sometimes convenient to use spin notation rather than particle (i.e., lattice
gas) notation in describing configurations in $X_k$ or $X$. As usual if $\eta$ is a particle variable
taking values in $\{0, 1\}$ we introduce a corresponding spin variable $\sigma = 2\eta - 1$ taking values in $\{-1, +1\}$. This is convenient in particular because it permits us to write a measure $\mu_k$ directly in terms of the corresponding spin correlations:

$$
\mu_k(\sigma_0, \ldots, \sigma_k) = 2^{-(k+1)} \left( 1 + \sum_{A \subset \Lambda_k, A \neq \emptyset} \langle \sigma_A \rangle \sigma_A \right),
$$

where as usual $\sigma_A = \prod_{i \in A} \sigma_i$ and the spin correlation $\langle \sigma_A \rangle$ denotes the expectation $\mu_k(\sigma_A)$ of $\sigma_A$ in the measure $\mu_k$. One may think of the expectations $\langle \sigma_A \rangle$ in (5) as parameters which determine the measure; the condition that $\mu_k$ be LTI is simply that $\langle \sigma_A \rangle = \langle \sigma_B \rangle$ whenever $B$ is a translate of $A$. Note, however, that in using the form (5) to construct a measure with certain given $\langle \sigma_A \rangle$ one must check that it assigns nonnegative probability to each configuration.

**Remark 3**

(a) If $\Omega$ is any finite set then everything said above extends immediately to measures defined on $\Omega^{\Lambda_k}$. As an example, take $\Omega = \{0, 1\}^{\Lambda_m}$ so that $\Omega^{\Lambda_k}$ may be identified with the space $\{0, 1\}^{\Lambda_k \times \Lambda_m}$ of particle configurations on a $k \times m$ rectangle. If such a measure is LTI under translations in the horizontal direction then it may be extended by an obvious generalization of (4) to a measure on configurations on $\Lambda \times \Lambda_m$, where $\Lambda$ is any interval containing $\Lambda_k$, and hence to a measure on configurations on $\mathbb{Z} \times \Lambda_m$ as in the proof of Theorem 1. However, even if the original measure is also LTI in the vertical direction, this extension procedure need not maintain the LTI property for translations in the vertical direction. Example 16 (see Sect. 6) is of this nature: an extension from the original $2 \times 2$ square to a $3 \times 2$ rectangle destroys the vertical LTI property.

(b) The extension method in the Markovian form (4) is well defined for a large class of spaces $\Omega$; it suffices that the $\mu_k(\eta_k \mid \eta_0, \ldots, \eta_{k-1})$ be well defined (regular) conditional probabilities. This will be true, for example, if $\Omega$ is a complete separable metric space [2] or, essentially equivalently, a standard Borel space [10]. Consider, for example, an LTI measure for a strip in $\mathbb{Z}^2$, that is, an LTI measure on $\{0, 1\}^{\mathbb{Z} \times \Lambda_m} = (\{0, 1\}^\mathbb{Z})^{\Lambda_m}$; since $\{0, 1\}^\mathbb{Z}$ is a standard Borel space we may then use (4) to extend vertically to a measure on configurations on $\{0, 1\}^{\mathbb{Z} \times \Lambda_m}$. In this context the original measure might be obtained by beginning with an LTI measure on a rectangle $\{0, 1\}^{\Lambda_k \times \Lambda_m}$ and making the maximal entropy extension in the horizontal direction. As noted above, in general the LTI property in the vertical direction will not be preserved by this extension, but if it is, the above remarks apply.

### 2.1 Entropy

Let us denote the Gibbs–Shannon entropy of a probability measure $\mu$ on a discrete set $Q$ (typically for us a set of configurations) by $S(\mu)$:

$$
S(\mu) = - \sum_{q \in Q} \mu(q) \log \mu(q).
$$

The entropy of the extension $\mu_j$ given in (3) or (4) is easily found to be

$$
S(\mu_j) = S(\mu_k) + (j - k)[S(\mu_k) - S(\mu_{k-1})], \quad j \geq k.
$$
Now recall the strong subadditivity inequality for entropy [20]: if \( \mu \) is a probability measure on a product \( Q = Q_1 \times Q_2 \times Q_3 \) then the marginal measures \( \mu_{12}, \mu_{23}, \) and \( \mu_2 \) on \( Q_1 \times Q_2, Q_2 \times Q_3, \) and \( Q_2 \), respectively, satisfy

\[
S(\mu) \leq S(\mu_{12}) + S(\mu_{23}) - S(\mu_2).
\]

This implies that if \( \nu_j \) is any measure on \( X_j \) for which the marginal \( \nu_j^{(i)} \) on \( \{0, 1\}^{[i,i+1,\ldots,i+k]} \) satisfies

\[
\nu_j^{(i)}(\eta_i, \ldots, \eta_{i+k}) = \mu_k(\eta_i, \ldots, \eta_{i+k}), \quad i = 0, 1, \ldots, j - k,
\]

then \( S(\nu_j) \) is at most equal to the right hand side of (7). Thus \( \mu_j \) is in fact the maximal entropy extension of \( \mu_k \) to \( X_j \) under the constraint (9); there is a unique such extension by the strict concavity of the entropy. Note that satisfaction of (9) is necessary for \( \nu_j \) to be LTI but is not sufficient, since it does not impose translation invariance for sets of diameter greater than \( k + 1 \). Nevertheless, we know from Theorem 1 that the measure \( \mu_j \), which maximizes the entropy under only the constraint (9), is LTI, so that the same measure would be obtained by maximizing the entropy over all LTI measures.

### 2.2 Gibbs Measures

Now suppose that \( \mu_k \) does not assign zero probability to any configuration. Then it is easy to see that the Markovian extension \( \mu \) on \( X \) provided by the proof of Theorem 1 is an infinite-volume Gibbs state (see [26] for definitions and results) for the translation invariant interaction energy \( U \) defined formally by

\[
U(\eta) = \sum_{i \in \mathbb{Z}} \Phi(\eta_i, \ldots, \eta_{i+k}), \quad \eta \in X,
\]

where the interaction potential \( \Phi \) is given by

\[
\Phi(\eta_0, \ldots, \eta_k) = -\ln \mu_k(\eta_k | \eta_0, \ldots, \eta_{k-1}).
\]

If \( \mu_k \) assigns zero measure to some configurations then the same arguments and conclusions apply. We may either simply allow for the interaction \( \Phi \) to sometimes be \( +\infty \) and consider the corresponding Gibbs states, or we may follow [26] and restrict the allowable configurations to those whose restriction to any interval of \( k + 1 \) sites has nonzero probability under \( \mu_k \).

Conversely, suppose that one starts with a TI measure \( \nu \) on \( X \) which is a Gibbs state for some interaction potential with interactions of range at most \( k \); again we may allow the interaction potential to take the value \( +\infty \) or alternatively may restrict the allowable configurations by local constraints of range \( k \). The marginal \( \nu_k \) of \( \nu \) on \( X_k \) will then be LTI. Since \( \nu \) is Gibbs, it is Markovian of range \( k \) [26] and hence agrees with the Markovian extension of \( \nu_k \) to \( X \) provided by the proof of Theorem 1. Note that the original interaction interaction in terms of which \( \nu \) is defined need not agree with the interaction (11) naturally associated the Markovian extension procedure applied to \( \nu_k \); different interactions will give the same Gibbs measure, and thus be essentially equivalent, if they give the same answer, up to a constant, when they are used to compute the energy in a finite volume with boundary condition (the constant may depend on the boundary condition) [11, Sect. 2.4].
Proof of Theorem 4
of symmetric measures.

$\phi^i$ of $T_i$ induces mapping $\phi$ of $T$.

Theorem 4
Let $\mu$ be an invariant measure on $X$. Then $\mu$ has an extension to an invariant measure $\mu$ on $X$.

3 Extension of Measures on the Bethe Lattice

As discussed in Remark 3a above, the Markovian extension technique of Sect. 2 does not in general yield extensions of measures in higher dimensions. It does do so, however, on the Bethe lattice. To discuss this we fix $q \geq 1$ and let $T$ denote the (infinite) Bethe lattice in which every vertex has degree $q + 1$. For a subgraph $H$ of $T$ we may then consider a measure $\mu_H$ on $X_H = \Omega_H$ and ask for an extension to $X = \Omega_T$ which is invariant under the group of all isomorphisms of $T$. Again there is an obviously necessary local invariance (LI) condition for the existence of such an extension: that if $H_1$ and $H_2$ are connected isomorphic subgraphs of $H$, with $\phi : H_1 \rightarrow H_2$ an isomorphism, and $\nu_j$ is the marginal of $\mu_H$ on $X_{Hj}$, then the induced mapping $\phi_\mu$ of measures satisfies $\phi_\mu \nu_2 = \nu_1$.

A special role in what follows will be played by full subgraphs of $T$: the maximal subgraphs of $T$ with fixed diameter $k$. Any two such are isomorphic (see Fig. 1). When $k$ is even, such a full subgraph has $(q + 1)$-fold symmetry about a central vertex; when $k$ is odd, it has 2-fold symmetry across a central edge. We fix some vertex $v_0$ in $T$ and some edge $e_0$ incident on it, and for $k = 0, 1, \ldots$ let $T_k$ denote the particular full subgraph which has central vertex $v_0$ if $k$ is even and central edge $e_0$ if $k$ is odd, so that in particular $T_0 \subset T_1 \subset \cdots$. We abbreviate $X_{Tk}$ as $X_k$. If $q = 1$ then the Bethe lattice $T$ is just $Z$ and $T_k$ is the interval $\Lambda_k$ of $k + 1$ sites. For general $q$ the graphs $T_k$ play a role for extensions to $T$ similar to that of the $\Lambda_k$ for extensions to $Z$: when one begins with an LI measure on $X_k$ there is no obstruction to extension.

Theorem 4
Let $\mu_k$ be an LI measure on $T_k$, $k = 0, 1, \ldots$. Then $\mu_k$ has an extension to an invariant measure $\mu$ on $X$.

Note that, because the invariance we consider for $T$ is invariance under all isomorphisms, the $q = 1$ case of Theorem 4 corresponds to the case in Theorem 1 of symmetric extensions of symmetric measures.

Proof of Theorem 4
We first extend $\mu_k$ to a measure $\mu_{k+1}$ on $T_{k+1}$; in doing so we will need only two consequences of the local invariance of $\mu_k$: (i) $\mu_k$ is invariant under automorphisms of $T_k$, and (ii) the marginal of $\mu_k$ on $X_{k-1}$ is invariant under automorphisms of $T_{k-1}$. (In fact, (i) and (ii) imply local invariance, but we do not need this.) $T_{k+1}$ contains $r_k$ copies $T_k^1, \ldots, T_k^{r_k}$ of $T_k$ (one of which is $T_k$ itself), where $r_k = 2$ if $k$ is even and $r_k = q + 1$ if $k$ is odd, and these intersect in $T_{k-1}$. From (i) it follows that we may speak without ambiguity of the copy $\mu_k^i$ of $\mu_k$ on $T_k^i$, and from (ii) that the marginal of any $\mu_k^i$ on $T_{k-1}$ is independent of $i$. Then the extension formula is

![Fig. 1 Full subgraphs of diameter k, k = 0, ..., 4, when q = 2](image-url)
\[
\mu_{k+1}(\eta) = \mu_k(\eta_{T_{k-1}})^{(r_k-1)} \prod_{i=1}^{r_k} \mu_i^j \left( \eta_{T_k^i} \right) 
\]
(12)
\[
\mu_k(\eta_{T_{k-1}}) \prod_{i=1}^{r_k} \mu_i^j \left( \eta_{T_k^i \setminus T_{k-1}} | \eta_{T_{k-1}} \right), 
\]
(13)
where for \( \eta \in X_{k+1} \) we have written \( \eta_H \) for the restriction of \( \eta \) to any subgraph \( H \) of \( T_{k+1} \). Note that (12) is a direct generalization of (2), while (13) is a symmetrized version of (3).

It is easy to see that \( \mu_{k+1} \) is indeed an extension of \( \mu_k \). Moreover, it again satisfies properties (i) and (ii); (i) follows from the fact that any automorphism of \( T_{k+1} \) will permute the \( T_k^i \) and preserve \( T_{k-1} \), and because \( \mu_{k+1} \) extends \( \mu_k \), (ii) is an immediate consequence of property (i) for \( \mu_k \). Thus we may apply the above construction repeatedly to extend \( \mu_k \) to any \( X_j \) with \( j > k \), maintaining properties (i) and (ii) at each step, and thus obtain the extension \( \mu \) on \( X \) as a limit. \( \mu \) is invariant under the group \( G \) of isomorphisms of \( T \), because, as is easily seen, \( G \) is generated by the subgroup \( G_{v_0} \) of \( G \) of isomorphisms that fix the central vertex \( v_0 \), together with the subgroup \( G_{e_0} \) of isomorphisms that fix the central edge \( e_0 \), and invariance of \( \mu \) under these subgroups follows from properties (i) and (ii) of the finite extensions.

**Remark 5** There is an alternative but equivalent version of the last step of this proof, that is, of the extension beyond \( X_{k+1} \). The procedure is of course again inductive; we consider the extension from \( X_j \) to \( X_{j+1} \), \( j \geq k+1 \). One obtains \( T_{j+1} \) from \( T_j \) by adding \( q \) new edges and vertices to each vertex \( v \) in a certain subset \( V_j \) of the vertices of \( T_j \) of degree one. Each such \( v \), together with the new edges and vertices attached to it, is part of a unique copy \( T_k^v \) of \( T_k \) in \( T_{j+1} \), and the extension is
\[
\mu_{j+1}(\eta) = \mu_j(\eta_{T_j}) \prod_{v \in V_j} \mu_k \left( \eta_{T_k^v \setminus H^v} | \eta_{H^v} \right), 
\]
(14)
where \( H^v = T_k^v \cap T_j \). Thus the distribution determined by \( \mu_{j+1} \) on the new vertices attached to \( v \) depends only on the configuration in \( H^v \). From this it follows that the distribution on the complement of any \( T_j \) which arises from conditioning the extension \( \mu \) on the configuration in \( T_j \), actually depends only on the configuration on vertices of \( T_j \) a distance at most \( k \) from the complement. In this sense the extension constructed here is maximally Markovian.

It is straightforward to calculate the entropy of these extensions, through the recurrence
\[
S(\mu_{j+1}) = S(\mu_j) + (r_j - 1)[S(\mu_j) - S(\mu_{j-1})], 
\]
(15)
where \( \mu_{k-1} \) is the marginal of \( \mu_k \) on \( X_{k-1} \). For \( q = 1 \) the entropy grows linearly with \( j \); see Sect. 2.1. For \( q \geq 2 \), \( S(\mu_j) \) grows as \( j^{q/2} \) for large \( j \); more specifically, with \( \Delta S = [S(\mu_k) - S(\mu_{k-1})] \) we find that for \( j \geq k \) and \( p = \lfloor (j - k + 1 - (k \text{ mod } 2))/2 \rfloor \),
\[
S(\mu_j) = S(\mu_k) + \frac{r_j + 1 + q^p - r_k + 1}{q - 1} q^{k \text{ mod } 2} \Delta S. 
\]
(16)
A simple calculation proves the existence of the thermodynamic limit of the entropy per site, and an argument as in Sect. 2.1 implies that (16) is the maximum possible entropy of any extension.

The considerations of Sect. 2.2 apply here essentially unchanged; in particular, the measure on \( \mathbb{T} \) constructed here is Gibbsian with interaction potential
\[
\Phi(\eta_{T_k}) = - \ln \mu_k \left( \eta_{T_k \setminus T_{k-1}} | \eta_{T_{k-1}} \right). 
\]
(17)
4 Periodic Extensions in One Dimension

We now turn again to the study of TI extensions to \( X = \Omega^Z \) of an LTI measure \( \mu_k \) defined on the space \( X_k \) of configurations on the interval \( \Lambda_k \). We consider in particular extensions which are of a different character from the maximal entropy extensions considered in Sect. 2: those supported on periodic configurations in \( X \). We will call such a measure a periodic configuration (PC) measure. Within the class of PC measures we single out the basic periodic configuration (BPC) measures: a BPC measure is obtained from a particular \( p \)-periodic configuration by giving weight \( 1/p \) to each of its \( p \) translates. The set of PC measures is clearly convex and its extreme points are the BPC measures; since the set of BPC measures is countable, every PC measure \( \nu \) has a representation

\[
\nu = \sum c_\alpha \nu_\alpha, \quad c_\alpha \geq 0, \quad \sum c_\alpha = 1,
\]

(18)

where the sums run over the set \( \{\nu_\alpha\} \) of all BPC measures.

In this section and the next we will for simplicity consider only the case of particle configurations, i.e., \( \Omega = \{0, 1\} \); the extension of the results to any finite \( \Omega \) is straightforward. We will write a configuration \( \eta \in X_k \) as a string \( \eta_0 \eta_1 \ldots \eta_k \) (rather than as a \((k + 1)\)-tuple \((\eta_0, \ldots, \eta_k)\)) and will similarly write \( \eta \in X \) as a doubly infinite string; since we do not use any products of the \( \eta \) no confusion should arise.

4.1 BPC and Extremal LTI Measures on \( X_k \)

Let \( M_k \) denote the set of all LTI probability measures on \( X_k \); \( M_k \) is manifestly a convex polytope. Since the LTI condition (1) and the normalization \( \sum_{\eta \in X_k} \mu_k(\eta) = 1 \) represent \( 2^k \) independent constraints on the \( 2^{k+1} \) variables \( \mu_k(\eta) \), \( \eta \in X_k \), \( M_k \) has dimension \( 2^k \).

We wish to characterize the extreme points of this polytope. We will say that a periodic configuration \( \eta \in X \) and the corresponding BPC measure \( \nu \) supported on the translates of \( \eta \) are \( k \)-primitive if no segment of length \( k \) is repeated within one (minimal) period \( p \) of \( \eta \), that is, if \( \eta_1 \eta_{i+1} \ldots \eta_j \eta_{j+k} = \eta_j \eta_{j+1} \ldots \eta_{j+k-1} \) only when \( j - i \) is a multiple of \( p \). Note that then \( p \leq 2^k \). We will prove shortly, using the concept of a de Bruijn graph, that the extreme points of \( M_k \) are precisely the marginals \( \pi_k \nu \) with \( \nu \) a \( k \)-primitive BPC measure.

The (binary) De Bruijn graph of order \( k \geq 1 \) (or sometimes dimension \( k \)) [9,13], \( G_k \), is the directed graph with \( 2^k \) vertices and \( 2^{k+1} \) edges, labeled respectively by all binary strings of length \( k \) and length \( k + 1 \), in which for any binary digits \( a \) and \( b \) and binary string \( \theta \) of length \( k - 1 \) the edge \( a \theta b \) runs from vertex \( a \theta \) to vertex \( \theta b \) (see Fig. 2). Note in particular that \( G_k \) contains two loops, labeled respectively by \( 00 \ldots 0 \) and \( 11 \ldots 1 \), but no multiple edges. Since the edges of \( G_k \) are labeled by the elements of \( X_k \), it is clear that any probability measure \( \mu_k \) on \( X_k \) corresponds to an assignment of a nonnegative current \( j_\eta \) to each edge \( \eta \) of \( G_k \) in such a way that \( \sum \eta j_\eta = 1 \); the correspondence is of course via \( j_\eta = \mu_k(\{\eta\}) \). The terminology “current” is appropriate because one checks easily that \( \mu_k \) is LTI if and only if the current is conserved at each vertex of \( G_k \), that is, if for each vertex \( \xi \) the sum of the currents on the two edges entering \( \xi \) is equal to the sum of the currents on the two edges leaving \( \xi \). (Such a current assignment is called a circulation in the theory of graphs.)

Suppose that \( \mathcal{P} \) is a closed path in \( G_k \), that is, a sequence of \( |\mathcal{P}| \) edges \( \eta^{(1)}, \ldots, \eta^{(|\mathcal{P}|)} \) in that order (possibly with repetitions), and that \( \mathcal{P} \) is minimal in the sense that there is no shorter closed path \( \mathcal{P}' \) such that \( \mathcal{P} \) is obtained by tracing \( \mathcal{P}' \) several times. Each \( \eta^{(j)} \) is a string of \( k + 1 \) symbols (see Fig. 2), and we may obtain from \( \mathcal{P} \) a periodic configuration by tracing \( \mathcal{P} \) repeatedly, recording the first symbol on each edge encountered: with \( \eta^{(j)} = \eta^{(j)}_0 \ldots \eta^{(j)}_k \)
The De Bruijn graphs \( G_1, G_2, \text{ and } G_3 \)

Fig. 2

this configuration is \( \{ \eta_0 \}^{(1)} \eta_0 \{ \eta_0 \}^{(1)} \eta_0 \ldots \in X \). Let \( v_P \) denote the BPC measure associated with this configuration; the map \( P \mapsto v_P \) establishes a bijective correspondence between minimal closed paths and BPC measures. As usual a cycle \( C \) in \( G_k \) is a closed path with no repeated vertices; a loop is a cycle with one edge and one vertex.

**Theorem 6**

The mapping \( C \mapsto v_C \) gives a bijective correspondence between the cycles in \( G_k \) and the \( k \)-primitive BPC measures on \( X \). The extreme points of \( M_k \) are precisely the marginals \( \pi_k v_C \), with \( C \) a cycle in \( G_k \); equivalently, every LTI measure \( \mu_k \) on \( X_k \) has the form \( \pi_k v \), where \( v \) is a (finite) convex combination of the \( k \)-primitive BPC measures \( v_C \). In particular, every such \( \mu_k \) has an extension to a PC measure.

**Proof**

The condition that a cycle \( C \) contain no repeated vertices is precisely the condition of \( k \)-primitivity on \( v_C \), and the bijective nature of the correspondence \( C \leftrightarrow v_C \) is clear. If \( |C| = p \) then the measure \( \pi_k v_C \) gives weight \( 1/p \) to each edge of \( C \) and weight 0 to all other edges, and is thus clearly an extreme point of \( M_k \). Conversely, given an element \( \mu_k \in M_k \), the set of edges \( \eta \) of \( G_k \) for which \( \mu_k(\eta) > 0 \) must by current conservation contain a cycle \( C \), say of length \( p \), and if \( \alpha \) is the smallest current assigned by \( \mu_k \) to any edge of \( C \) then we may write

\[
\mu_k = (p\alpha)\pi_k v_C + (1 - p\alpha)\mu_k^*, \quad \text{where} \quad \mu_k^* = \frac{1}{1 - p\alpha}(\mu_k - p\alpha\pi_k v_C),
\]

(19)

thus representing \( \mu_k \) as a convex combination of the LTI probability measures \( v_C \) and \( \mu_k^* \). We may apply the same construction to \( \mu_k^* \) and by repeating this process obtain a representation of \( \mu_k \) as a convex combination

\[
\mu_k = \sum_C \beta_C \pi_k v_C, \quad \sum_C \beta_C = 1,
\]

(20)

as required; the process must terminate because \( \mu_k^* \) as defined by (19) gives zero probability to at least one more configuration than does \( \mu \).

\( \Box \)

**Remark 7** (a) It is known [12,21] that \( G_k \) contains cycles with every length \( p \) satisfying \( 1 \leq p \leq 2^k \). In particular, \( G_k \) contains two cycles of length 1, the loops mentioned above, which correspond to the two period-one configurations in \( X \), and \( 2(2^k - 1 - k) \) cycles of length \( 2^k \) [9].
Although it follows from (a) that \( M_k \) contains at least \( 2^{(2^k-1-k)} \) extreme points, a result of Carathéodory [5, 14] implies that, because \( M_k \) is of dimension \( 2^k \), every LTI measure \( \mu_k \) can be written as a convex combination of at most \( 2^k + 1 \) measures \( \pi_k \nu_C \).

### 4.2 Extensions of LTI Measures to a Ring

Let \( \mathbb{Z}_L \) denote the ring (one-dimensional discrete torus) with \( L \) sites: \( \mathbb{Z}_L = \{0, \ldots, L-1\} \), with translation defined via periodic boundary conditions. Rather than considering extensions of \( \mu_k \) to TI measures on \( X \) one may instead ask whether there exists an integer \( L \geq k + 1 \) such that \( \mu_k \) has an extension to a TI measure on \( Y_L = \{0,1\}^\mathbb{Z}_L \), the set of configurations on \( \mathbb{Z}_L \), and, if so, for what values of \( L \) this is true. The first question is clearly equivalent to that of whether there is an extension to a measure \( \nu \) on \( \mathbb{Z} \) which is a convex combination of a finite number of BPC measures; if so, \( L \) may then be taken to be the least common multiple of their periods. Theorem 6 implies that the answer is affirmative; here we discuss a few questions about the values of \( L \).

**Theorem 8** The smallest integer \( L \geq k + 1 \) such that every LTI measure on \( X_k \) may be extended to a TI measure on \( Y_L \) is

\[
L_0(k) = \text{lcm}\left\{1, 2, 3, \ldots, 2^k - 1, 2^k\right\}. \tag{21}
\]

**Proof** Suppose that \( L \geq k + 1 \). It is easy to see that the measure \( \nu_C \), with \( C \) a cycle in \( G_k \), can be extended to a TI measure on \( Y_L \) if and only if \( |C| \) divides \( L \), and from the representation (20) it follows that every LTI measure on \( X_k \) can be extended if and only if \( L \) is divisible by \( |C| \) for every cycle \( C \). The result (21) now follows from Remark 7a.

Theorem 8 does not address the natural question of the minimal value of \( L \), or of all possible values of \( L \), for the extension of a given measure \( \mu_k \). We will not try to give a general discussion of this matter, but rather content ourselves with discussing two examples.

**Example 9** Suppose that we begin with a measure \( \mu_1 \) defined on two sites. The De Bruijn graph \( G_1 \) has three cycles \( C_0, C_1, C_2 \) (see Fig. 2), where \( C_0 \) and \( C_1 \) denote the loops \( 00 \) and \( 11 \) respectively, and \( C_2 \) the cycle with edges \( 01 \) and \( 10 \), so that \( \mu_1 = \sum_{i=0}^{2} c_i \pi_i \nu_C \), with coefficients in the simplex \( \Sigma = \{(c_0, c_1, c_2) \mid c_i \geq 0, \sum_{i=0}^{2} c_i = 1\} \). \( \mu_1 \) has a TI extension to \( Y_L \) for any even \( L \), since the measures corresponding to the three extreme points \( (1, 0, 0), (0, 1, 0), \) and \( (0, 0, 1) \) of \( \Sigma \) have extensions which give respectively probability one to \( 0^L \), probability one to \( 1^L \), and probability one half to each of \( 01^{L/2} \) and \( 10^{L/2} \) (where for any finite binary string \( \eta, \eta^n \) denotes the concatenation of \( n \) copies of \( \eta \)). If \( L \) is odd, say \( L = 2\ell + 1 \), then \( \mu_1 \) has an extension to \( Y_L \) if and only if \( c_2 \leq 1 - 1/L \). For the measures corresponding to the four extreme points \( (1, 0, 0), (0, 1, 0), (1/L, 0, 1 - 1/L), \) and \( (0, 1/L, 1 - 1/L) \) of \( \Sigma \cap \{(c_0, c_1, c_2) \mid c_2 \leq 1 - 1/L\} \) all have extensions to \( Y_L \); the first two are as above and the remaining two give probability \( 1/L \) to each of the \( L \) translates of \( 0(01)^\ell \) and \( 1(01)^\ell \), respectively. Conversely, if \( L \) is odd and \( \mu_1 \) has a TI extension to \( Y_L \) then the fact that every configuration in \( Y_L \) contains either two consecutive 1’s or two consecutive 0’s implies that \( c_0 + c_1 \geq 1/L \).

**Example 10** If \( \mu_k \) is supported on a union of vertex disjoint cycles (and gives positive probability to each) then an analysis as in the proof of Theorem 8 shows that \( \mu_k \) has an extension to \( Y_L \) if and only if \( L \) is divisible by the least common multiple of the lengths of these cycles. The maximal length of a cycle is \( 2^k \) (see Remark 7a), but this least common multiple may
be much larger. Using Maple, we find that for \( k = 1, \ldots, 7 \) the maximum value \( L_k \) of this least common multiple, taken over all collections of vertex disjoint cycles, is as given in Table 1; there the factorization corresponds to the lengths of the maximizing set of cycles. In all of these cases except \( k = 3 \), \( L_k = g(2^k) \), where \( g \) is Landau’s function [19]: \( g(n) \) is the maximum, over all partitions \( \{n_1, \ldots, n_q\} \) of \( n \), of \( \text{lcm}\{n_i, \ldots, n_q\} \). Landau showed that 
\[
\log g(n) \sim \sqrt{n \log n}
\]
for large \( n \). We do not know whether \( L_k = g(2^k) \) for some or all \( k \geq 8 \); the question is whether or not there exists a set of vertex-disjoint cycles in \( G_k \) whose lengths are given by the maximizing partition of \( 2^k \).

5 Minimal Entropy Extensions

In this section we consider TI extensions \( \mu \) of \( \mu_k \) with finite total entropy, where the total entropy of any TI measure \( \mu \) on \( X \) is defined by
\[
S(\mu) = \lim_{j \to \infty} S(\pi_j \mu),
\]
with the entropy \( S(\pi_j \mu) \) given by (6). The TI extensions described in Theorem 6 clearly have finite entropy. We begin with a partial converse.

Lemma 11 Every TI measure \( \mu \) on \( X \) with finite total entropy is a PC measure.

Proof Let \( \mu \) be a TI measure on \( X \). Since any configuration \( \eta \) with \( \mu(\eta) > 0 \) must be periodic, \( \mu \) is atomic if and only if it is a PC measure. Suppose then that \( \mu \) is not atomic, so that \( \mu = t \mu_a + (1 - t) \mu_b \) with \( 0 \leq t < 1 \), \( \mu_a \) an atomic probability measure, and \( \mu_b \) a nonatomic probability measure. Because \( \mu_b \) is nonatomic there must exist, for any \( n \geq 1 \), a partition \( X = \bigcup_{i=1}^{n} A_i \) with the \( A_i \) measurable sets satisfying \( \mu_b(A_i) = 1/n \) [15, p. 174]. Then one can approximate the \( A_i \) arbitrarily closely by disjoint cylinder sets \( A_i' \), where for some large \( N \), \( A_i' = \pi_{[-N,N]}^{-1}(B_i) \) with \( B_i \subset X_{[-N,N]} \). In particular, one can make this approximation sufficiently close that
\[
S(\pi_{[-N,N]}^{-1} \mu_b) \geq \sum_{i=1}^{n} (\pi_{[-N,N]}^{-1} \mu_b)(B_i) \log (\pi_{[-N,N]}^{-1} \mu_b)(B_i)
\]
\[
\geq -\frac{1}{2} \sum_{i=1}^{n} \mu_b(A_i) \log \mu_b(A_i)
\]
\[
= \frac{1}{2} \log n.
\]
Thus $\mu_b$ and hence also $\mu$ does not have finite (total) entropy. 

Now let $\mu_k$ be an LTI measure on $X_k$; from Lemma 11 and the discussion in Sect. 4.1 we know that every finite entropy extension $v$ of $\mu_k$ has the form

$$v = \sum_P c_P v_P, \quad c_P \geq 0, \quad \sum_P c_P = 1,$$

where the sum is over some collection of minimal closed paths in $G_k$. Note that the BPC measure $v_P$ has entropy $S(v_P) = \log |P|$ and that the measure $v$ of (24) has entropy

$$S(v) = \sum_P c_P (\log |P| - \log c_P).$$

(25)

**Theorem 12** Let $\mu_k$ be an LTI measure on $X_k$. Then $\mu_k$ has at least one (TI) extension of minimal entropy of the form

$$\hat{\mu} = \sum_{i=0}^{2^k} c_i \nu_{C_i}, \quad c_i \geq 0, \quad \sum_{i=0}^{2^k} c_k = 1,$$

(26)

for some cycles $C_0, \ldots, C_{2^k}$ in $G_k$.

**Proof** We will first show that an entropy-minimizing extension exists, then that there is such a measure with the form (24) having $c_P > 0$ only if $P$ is a cycle, and finally that there is such a minimizing measure which is a convex combination of at most $2^k + 1$ measures $\nu_C$, with $C$ a cycle. Let $M$ be the space of all TI probability measures on $X$ which extend $\mu_k$. Then, in the weak topology, $M$ is compact and moreover (22) exhibits $S$ as the increasing limit of functions continuous on $M$; thus $S$ is lower semi-continuous on $M$ and so achieves its minimum there. Each minimizing measure will have the form (24).

Now we show that there is a minimizing measure in the form (24) for which each closed path appearing with nonzero coefficient is a cycle. To do so we note that among all the minimizing measures we can choose one, say

$$\tilde{\mu} = \sum_P \tilde{c}_P v_P, \quad \tilde{c}_P \geq 0, \quad \sum_P \tilde{c}_P = 1,$$

(27)

which contains, among the (minimal) closed paths $P$ with $\tilde{c}_P > 0$, the maximal number of cycles. Then in fact all the $P$ in (27) for which $\tilde{c}_P > 0$ must be cycles. For if there is some such path $\tilde{P}$ which is not a cycle it may be decomposed into a cycle $\tilde{C}$ and some remaining path $P'$ edge-disjoint from $\tilde{C}$. If now in (27) we make the replacement

$$\tilde{c}_{\tilde{P}} v_{\tilde{P}} \rightarrow \frac{|\tilde{C}|}{|P|} \tilde{c}_{\tilde{P}} v_{\tilde{C}} + \frac{|P'|}{|P|} \tilde{c}_{\tilde{P}} v_{P'},$$

(28)

then $\pi_k \tilde{\mu}$ is unchanged and a simple computation shows that $S(\tilde{\mu})$ does not increase. By choice of $\tilde{\mu}$, then, $\tilde{C}$ must appear in (27) with positive coefficient. But then the same computation shows that $S(\tilde{\mu})$ must strictly decrease under (28), contradicting its minimality.

To complete the proof we suppose that $N$ is the minimum number of cycles needed to express an entropy-minimizing extension of $\mu_k$ in the form $\tilde{\mu} = \sum_{i=0}^N a_i \nu_{C_i}, a_i > 0$, assume that $N > 2^k + 1$, and derive a contradiction. Now certainly $\mu_k = \sum_{i=0}^N a_i \pi_k \nu_{C_i}$, and it then follows from the proof in [14] of the Carathéodory result mentioned in Remark 7(b) that
(possibly after renumbering the cycles) we may also write \( \mu_k = \sum_{i=0}^{N-1} a_i^* \pi_k v_{C_i} \) for some nonnegative coefficients \( a_i^* \). Set \( a_N^* = 0 \) and consider the measure

\[
\tilde{\mu}(t) = \sum_{i=0}^{N} a_i(t) v_{C_i}, \quad a_i(t) = (1-t)a_i + ta_i^*,
\]

and let \([u, 1]\), with \( u < 0 \), be the maximal interval such that \( a_i(t) \geq 0 \) for \( i = 0, \ldots, N \) if \( t \in [u, 1] \). Note then that \( \pi_k \tilde{\mu}(t) = \mu_k \) for \( t \in [u, 1] \) and that the entropy \( S(\tilde{\mu}(t)) \), which is concave in \( t \), achieves its minimum at \( t = 0 \), and hence is constant. Thus \( S(\tilde{\mu}(1)) = S(\tilde{\mu}) \), contradicting the minimality of \( N \).

\[ \square \]

Remark 13 (a) The argument of the second step in the proof of Theorem 12 may be used to strengthen the conclusion expressed in (24) by showing that in fact every entropy-minimizing extension of \( \mu_k \) must be a finite convex combination of BPC measures.

(b) From (25) and (26) it follows easily that the entropy of a minimal entropy extension of \( \mu_k \) can be at most \((2^k + 1)[\log 2^k + \log(2^k + 1)]\).

Theorem 12 reduces the search for a minimal entropy extension of a given \( \mu_k \) to a finite problem: for each set of \( 2^k + 1 \) cycles in \( G_k \) one tests whether \( \mu_k \) is a convex combination of the measures \( \pi_k v_C \) for cycles \( C \) in that set; if it is, the coefficients are uniquely determined and one may compute the entropy of the corresponding combination of the \( v_C \). One then chooses the minimum entropy among the latter. However, this is not practical for \( k \) very large, and we have no better approach at the moment.

There is, however, one case in which the minimal entropy extension of \( \mu_k \) may be obtained explicitly. Suppose that \( \mu_k \) is such that there is a bijective measure preserving mapping \( \phi : X_k \to X_k \) which for each vertex \( \xi \) of \( G_k \), \( \xi \in X_{k-1} \), maps the set of edges entering \( \xi \) to the set of edges leaving \( \xi \), that is, \( \phi([0\xi, 1\xi)) = [\xi 0, \xi 1) \). Then \( \phi \) determines a set of pairwise edge-disjoint paths \( P_1, \ldots, P_n \) by the condition that if \( \eta^{(1)}, \ldots, \eta^{(|P_1|)} \) are the edges of \( P_1 \) in order then \( \eta^{(j+1)} = \phi(\eta^{(j)}) \), \( j = 1, \ldots, |P_1| - 1 \), and \( \phi(\eta^{(|P_1|)}) = \eta^{(1)} \). Now because \( \phi \) is measure preserving, \( \mu_k \) gives equal weight to the edges of each \( P_1 \), and thus the measure \( \sum_{i=1}^{n} w_i |P_i| v_{P_i} \), where \( w_i = \mu_k(\eta) \) for any edge \( \eta \) of \( P_i \), is an extension of \( \mu_k \) with the same entropy as \( \mu_k \) and is thus the minimal entropy extension. This is precisely the case in which \( \mu_k \) has a TI extension that is \((k + 1)\)-deterministic, in the sense that is is supported on configurations that are determined by any segment of length \( k + 1 \).

A special case of the above occurs when \( \mu_k \) is supported on a set of pairwise vertex-disjoint cycles \( C_1, \ldots, C_n \); this means that for each vertex of \( G_k \) at most one incoming and one outgoing edge is assigned positive probability by \( \mu_k \). Then \( \mu_k \) has the unique TI extension \( \sum w_i |C_i| v_{C_i} \), with \( w_i \) as above. In particular, the maximal entropy extension of Theorem 12 are the same. The total entropy of the extension is the entropy of \( \mu_k \), so that one sees from (7) (or directly) that this is also the entropy of the restriction \( \mu_{k-1} \) of \( \mu_k \) to \( X_{k-1} \). The TI extension in this case is \( k \)-deterministic.

Remark 14 One might try to obtain a minimum entropy extension of \( \mu_k \) by a step-by-step procedure, extending first to a measure \( \mu_{k+1} \) on \( X_{k+1} \), then to \( \mu_{k+2} \) on \( X_{k+2} \), etc., choosing at each step the minimum entropy extension for that step. In fact, there is a simple algorithm for each single step, but the procedure may not produce the extension with the minimal total entropy, even for the case \( k = 2 \). We omit details.
6 Nonextendible LTI Measures

In this section we give examples to show that the local invariance condition (LTI or, for the Bethe lattice, LI) is in general not sufficient for extension to an invariant measure, unless $\Lambda$ is an interval in $\mathbb{Z}$, a strip in $\mathbb{Z}^2$, a higher-dimensional analogue of the latter, or a full subgraph of the Bethe lattice.

**Example 15** (a) Let $\Lambda = \{0, 1, 3\} \subset \mathbb{Z}$ and $\Omega = \{\circ, \bullet\}$, and suppose that $\mu_\Lambda$ assigns probability 1/2 to each of the two configurations $(\bullet, \bullet, \circ, \circ)$ and $(\circ, \circ, \circ, \bullet)$. Then $\mu_\Lambda$ is LTI but does not even have an LTI extension to the interval $\{0, 1, 2, 3\}$, and hence not a TI extension to $\mathbb{Z}$.

(b) We may give a similar example for the Bethe lattice, again with $\Omega = \{\circ, \bullet\}$. In the notation of Sect. 3 we take $q = 2$ and let $H$ be one of the connected subgraphs of $T_2$ with three vertices. Then the measure which assigns probability $1/4$ to each of the configurations $\overset{123}{\circ\bullet\bullet}$, $\overset{123}{\bullet\circ\circ}$, $\overset{123}{\bullet\bullet\circ}$, and $\overset{123}{\circ\circ\bullet}$ is LI but does not extend to an LI measure on $X_2$.

Note that when $\Lambda \subset \mathbb{Z}$ and $\Lambda_k$ is the minimal interval containing $\Lambda$, the extendibility of an LTI measure from $X_\Lambda$ to $X_k$, which is necessary and, by Theorem 1, sufficient for extendibility to $X$, may be determined by solving a standard linear programming feasibility problem. If $H$ is a finite subgraph of $\mathbb{T}$ then a similar remark applies to the extension of an LI measure from $X_H$ to $X_T$, where $T$ is the minimal full subgraph of $\mathbb{T}$ containing $H$. Thus the problem of extension in one dimension, or on the Bethe lattice, is decidable; this is in contrast to the situation in higher dimension, as discussed in Sect. 7.

**Example 16** Let $\Lambda$ be a $2 \times 2$ square in $\mathbb{Z}^2$, let $\Omega = \{\circ, \bullet\}$, and let $\mu$ be the measure which assigns probability $1/4$ to each of the configurations $\eta^{(i)}$, $i = 1, \ldots, 4$, shown in Fig. 3. $\mu$ is LTI, since the marginal on the top, bottom, left, or right two sites of $\Lambda$ is Bernoulli with parameter $1/2$, but $\mu$ cannot be extended to a measure $\mu'$ on configurations on a $3 \times 3$ square $\Lambda'$ containing $\Lambda$. For suppose that $\mu'$ is such an extension; $\mu'$ can give positive probability to a configuration $\eta'$ only if the restriction of $\eta'$ to each of the four $2 \times 2$ subsquares of $\Lambda'$ is one of the $\eta^{(i)}$. Moreover, there must be an $\eta'$ with $\mu'(\eta') > 0$ having restriction $\eta^{(1)}$ to the lower left subsquare, and $\eta'$ must then have restrictions $\eta^{(3)}$ and $\eta^{(4)}$ to the upper left and lower right subsquares, respectively. But then the restriction of $\eta'$ to upper right subsquare will not be one of the $\eta^{(i)}$, whether or not the upper right hand site of $\Lambda'$ is occupied in $\eta'$.

The measure $\mu$ in Example 16 is not invariant under any of the symmetry operations of the square; one could hope that the imposition of some symmetry might give extensibility. The next example shows that this is not the case.

**Example 17** Let $\Lambda$ be a $3 \times 3$ square in $\mathbb{Z}^2$ and let $\mu$ be the measure which assigns probability $1/7$ to each of the configurations $\eta^{(i)}$, $i = 1, \ldots, 7$, shown in Fig. 4. $\mu$ is easily seen to be LTI and is clearly invariant under any symmetry of the square. However, $\mu$ cannot be extended to any $4 \times 4$ square $\Lambda'$ containing $\Lambda$. The proof is similar to the proof of nonextendibility given in Example 16: one checks, for example, that there is no configuration $\eta'$ in $\Lambda'$ which reduces to $\eta^{(2)}$ in the lower left hand $3 \times 3$ subsquare and to one of the $\eta^{(i)}$ in all the other $3 \times 3$ subsquares.
The measures in the above examples appear rather special, in that they assign zero probability to most configurations. Recall from Sect. 1, however, that the set of nonextendible measures (for fixed $\Lambda$) is open; thus small perturbations of these measures will also be nonextendible. Such perturbations may be taken to assign nonzero probability to every configuration in $\Lambda$, to be again LTI, and, for Example 17, to have all the symmetries of the square.

7 Undecidability

As discussed above, the situation in $\mathbb{Z}^d$ for $d \geq 2$ is quite different from that for $d = 1$ or for the Bethe lattice. In particular, there is no formula similar to (4) or (13) for an extension, and the LTI condition is not sufficient for extendibility. More surprisingly, the extendibility problem for $\mathbb{Z}^d$ with $d \geq 2$ is in several senses undecidable. To discuss this we introduce the idea of tiling. It suffices to fix $\Lambda$ to be a $2 \times 2$ box in $\mathbb{Z}^2$, and we will do so throughout this section. Let $Y$ be a finite subset of $X_\Lambda = \Omega^\Lambda$ constructed with some $\Omega$; we call the elements of $Y$ tiles and say that $Y$ tiles the plane if there is a configuration in $X$ whose restriction to every $2 \times 2$ box is an element of $Y$. Here we do not consider $\Omega$ as fixed, so there is an infinite number of possible sets $Y$ of tiles; given $Y$ we will consider only tilings by $Y$, so that for all practical purposes $Y$ determines $\Omega$, and we will omit mention of the latter in what follows. Berger [3] proved:

**Theorem 18** The tiling problem is undecidable: there is no decision procedure which, given a set of tiles $Y$, determines whether or not $Y$ tiles the plane.

The statement of the theorem means that there is no algorithm (or Turing machine) to which we can submit a tile set $Y$ and which will then yield the result “tiles” when $Y$ in fact tiles and “does not tile” when it does not. Note that it is crucial here that the set of possible tile sets $Y$ be infinite, since otherwise there would exist such a decision procedure, though we might not know what it is: if there were $N$ tile sets $Y_1, \ldots, Y_N$ then it would be one of the $2^N$ procedures which answer the $N$ questions “Does $Y_k$ tile?” in all $2^N$ possible ways.

We should remark that Berger worked with a different sort of tile, originally introduced by Wang [32], but it is easy to see [30] that his result implies the above theorem. A simplified version of the proof of Berger’s theorem is due to Robinson [25].

There is an alternative formulation of undecidability which follows from Berger’s result.

**Corollary 19** There exists a set of tiles $Y_*$ such that $Y_*$ tiles the plane but cannot be proved to do so.

**Proof** It is known [25] that if $Y$ does not tile the plane then there is some finite rectangle which it does not tile, so that the fact that $Y$ does not tile is provable. Thus if the conclusion of the theorem were false an algorithm generating all provable theorems would provide a decision procedure for the tiling problem. □
It should be noted that Corollary 19 is not really stated precisely; whether or not $Y$ can be proved to tile depends on the axiom system on which the proof is to be based. In fact, however, a tile set $Y_*$ satisfying the theorem will always exist, but will in general depend on the (consistent and sound) axiom system chosen.

Schlijper [30] observed a connection between the tiling problem and the extendibility of measures:

**Theorem 20** (Schlijper) A set of tiles $Y$ tiles the plane if and only if there exists an extendible measure $\nu_Y$ on $X_\Lambda$ with support $Y$.

Then an undecidability result follows:

**Corollary 21** There is no decision procedure which, given a set of tiles $Y$, determines whether or not there exists an extendible measure $\nu_\Lambda$ on $X_\Lambda$ with support $Y$. Equivalently, there is no decision procedure which, given an LTI measure $\mu_\Lambda$ on $X_\Lambda$, determines whether or not there exists an extendible measure $\nu_\Lambda$ on $X_\Lambda$ with the same support.

This result certainly suggests that there should be no decision procedure for our original problem of determining whether or not a given LTI measure $\mu_\Lambda$ is extendible, that is, that this problem is undecidable. However, since most of the measures $\mu_\Lambda$ are presumably not expressible—not computable—most cannot in fact be “given” to the decision procedure to begin with.

Nevertheless, Corollary 21 does lead to a conclusion which furnishes a strong sense of undecidability for the original problem. Suppose there were a condition $C$ for extendibility which was “useful”, that is, simpler and more transparent than extendibility itself—perhaps something in the nature of the LTI condition (although of course we know that this is not a such a condition for $d \geq 2$). No matter how simple $C$ were, however, there could exist no decision procedure which, given a set $Y$ of tiles, would determine whether or not there exists a measure $\nu_\Lambda$ on $X_\Lambda$ with support $Y$ which satisfies $C$.

Another formulation of undecidability for the extension problem, alternative to Corollary 21 in the sense that Corollary 19 is alternative to Theorem 18, follows immediately from Corollary 19 and Theorem 20:

**Corollary 22** There exists a set of tiles $Y_*$ such that (1) there is an extendible measure $\nu_\Lambda$ on $X_\Lambda$ with support $Y_*$, but (2) this fact cannot be proven.

Here, as for Corollary 19, $Y_*$ will in general depend on the axiom system to be used in the proof. It of course follows from Corollary 22 that if we specify a measure on $X_\Lambda$ with support $Y_*$ to arbitrary but not perfect precision—that is, specify that it lie in some arbitrarily small set of measures—then for some such specification there exists an extendible measure satisfying it whose existence can’t be proven. This suggests that there exists an extendible measure $\nu_\Lambda$ on $X_\Lambda$ for which the proposition that it is extendible can’t be proven. However this is not so clear, since the relevant measure may not be suitably expressible and thus the desired proposition may not exist.

As with Corollary 21, however, Corollary 22 does have a consequence which strongly suggests undecidability for the original problem: if there were a condition $C$ for extendibility, “useful” in the sense discussed above, then the statement that there exists a measure with support $Y_*$ which satisfies $C$ would be true but unprovable.
