Abstract

We investigate the sensitivity of the next generation of flavor-based low-energy experiments to probe the supersymmetric parameter space in the context of the phenomenological MSSM (pMSSM), and examine the complementarity with direct searches for Supersymmetry at the 13 TeV LHC in a quantitative manner. To this end, we enlarge the previously studied pMSSM parameter space to include all physical non-zero CP-violating phases, namely those associated with the gaugino mass parameters, Higgsino mass parameter, and the tri-linear couplings of the top quark, bottom quark and tau lepton. We find that future electric dipole moment and flavor measurements can have a strong impact on the viability of these models even if the sparticle spectrum is out of reach of the 13 TeV LHC. In particular, the lack of positive signals in future low-energy probes would exclude values of the phases between $O(10^{-2})$ and $O(10^{-1})$. We also find regions of parameter space where large phases remain allowed due to cancellations. Most interestingly, in some rare processes, such as $\text{BR}(B_s \to \mu^+\mu^-)$, we find that contributions arising from CP-violating phases can bring the potentially large SUSY contributions into better agreement with experiment and Standard Model predictions.

1 Introduction

The virtual effects of new interactions provide an important window of opportunity to probe the presence of physics beyond the Standard Model (SM). In particular, measurements of flavor-changing and CP-violating processes yield stringent tests of the SM at the quantum loop-level [1–6], and are potentially sensitive to new physics at scales far beyond the reach attainable at colliders in the foreseeable future. For example, constraints on new contributions to the four-quark operators that mediate neutral meson mixing place severe bounds on a new physics scale of up to $10^{3–5}$ TeV for unit coupling strength. Alternatively, if new interactions are present at the TeV-scale, these limits constrain the effective coupling strength to be below $10^{-11}$ to $10^{-5}$ [1].

The power of low-energy measurements in constraining UV-complete theories is best illustrated by the strong limit on sfermion masses in Supersymmetry (SUSY) theories [7–11]. In particular, the Charge-Parity (CP)-conserving and CP-violating observables in meson mixing, together with constraints on the electric dipole moment of the neutron and electron, exclude TeV-scale SUSY breaking parameters if the CP-violating phases and sfermion mixing angles are of order 1 [12–16]. For example, constraints from neutral kaon mixing require squarks to be heavier than $\sim 500$ TeV if the squark mass matrices have an anarchic flavor structure. Clearly, a viable model of TeV-scale Supersymmetry requires a specific flavor structure to accommodate the data; such structures are in fact present in many specific models of SUSY breaking [17–20]. Despite the necessary presence of a flavor structure that suppresses Supersymmetric contributions to experimental observables, next-generation flavor experiments will be sensitive to TeV-scale SUSY, as the mechanisms suppressing flavor and CP violation are not completely effective at the level of expected experimental sensitivity. In addition, if Supersymmetry is discovered via direct production at the LHC, then measurements in the flavor sector will be essential to determine the flavor structure of the underlying theory. Conversely, flavor experiments may provide a discovery path, having sensitivity to TeV-scale SUSY scenarios that are difficult to observe at the LHC. It is thus imperative to perform a comprehensive analysis to examine the sensitivity of future flavor experiments to terascale Supersymmetry, and compare that to expectations for Run II at the LHC.

In order to be inclusive and avoid prejudice on the modelling of physics at the high-scale, we examine terascale SUSY in a general framework that captures the phenomenology of a variety of SUSY-breaking models, as well as that of SUSY-breaking mechanisms which remain to be discovered. We thus consider the phenomenological Minimal Supersymmetric Standard Model (pMSSM) [21, 22], a subspace of the MSSM designed to examine regions of parameter space that have been unexplored in studies of more simplified models. The pMSSM is constructed from the general R-parity conserving MSSM by imposing the following set of data-driven assumptions: (i) No new sources of CP violation, (ii) Minimal Flavor Violation at the electroweak scale so that flavor violation is proportional to the CKM mixing matrix elements, (iii) degenerate 1st and 2nd generation sfermion masses, and (iv) negligible Yukawa couplings and $A$-terms for the first two generations. This results in a 19-dimensional parameter space, containing ten scalar masses, three gaugino masses, $M_{1,2,3}$, the three third generation $A_{t,b,\tau}$-terms, and three parameters related to the SUSY Higgs potential $\mu$, $M_A$ and $\tan \beta$. 

In order to examine the pMSSM contributions to CP-violating observables in this study, we augment the parameter space to include non-zero CP-violating phases. Including non-vanishing CP phases is particularly interesting because of their possible role in baryogenesis, as well as their potential to slightly increase the predicted value of the light Higgs mass within SUSY [23]. In particular, CP-violating phases can relieve some of the tension between the requirement of heavy stops and/or large stop mixing needed to generate the observed Higgs mass, versus the light stops and small mixing preferred by naturalness. Specifically, we explore the effect of including all six CP-violating phases that are consistent with the pMSSM assumption of minimal flavor violation: $\phi_1 \equiv \text{arg}(M_1)$, $\phi_2 \equiv \text{arg}(M_2)$, $\phi_\mu \equiv \text{arg}(\mu)$, $\phi_t \equiv \text{arg}(A_t)$, $\phi_b \equiv \text{arg}(A_b)$, and $\phi_\tau \equiv \text{arg}(A_\tau)$. We then study the effects of these non-zero phases on a variety of CP-conserving and CP-violating processes. We find that flavor observables place important constraints on the allowed soft SUSY breaking parameters, despite the assumptions (ii)-(iv) listed above. Interestingly, in some rare processes, such as $\text{BR}(B_s \rightarrow \mu^+\mu^-)$, we find that the inclusion of CP-phases can have the effect of bringing the SUSY contributions more in line with SM expectations, and hence in better agreement with experiment. We will see that flavor constraints on the CP-extended pMSSM provide an additional handle that could allow SUSY to be discovered by the next generation of low-energy experiments, even if the sparticle spectrum is out of kinematic reach at the LHC. Such low-energy experiments are thus seen as complementary to the direct LHC SUSY searches in a manner similar to both the direct and indirect searches for Dark Matter [24]. This work expands upon the Snowmass study presented in [25].

2 Analysis Procedure

For this study, we extend the CP-conserving pMSSM model sample produced in [26] which contains a neutralino lightest supersymmetric particle (LSP). This sample corresponds to a set of models (i.e., points in the parameter space), generated by a random scan employing flat priors over the 19 pMSSM parameters. The scan ranges, shown in Table I, were selected to enable phenomenological studies at the 14 TeV LHC. These models were subjected to a global set of collider, flavor, precision electroweak, dark matter, and theoretical constraints. We note that the WMAP/Planck measurement of the dark matter relic density was only employed as an upper bound, so that the LSP need not saturate this value, allowing for the possibility of multi-component dark matter. This procedure generated \( \sim 225k \) pMSSM models that can be adopted for further studies. The signatures of this model sample at the 7, 8, and 14 TeV LHC were recently examined in [27] using a fast Monte Carlo simulation of the ATLAS SUSY analysis suite. In that work, the expected ability of ATLAS to observe each model for each center-of-mass energy was determined. In particular, it was found that models with light squarks and gluinos remain viable after the LHC Run I at 7 and 8 TeV. These collider results will enable the comparison of the discovery reach between direct searches at the 14 TeV LHC and indirect effects in future low-energy precision measurements.

To extend this previous study to include CP-violating phases, we choose a random subset of 1000 models from this large pMSSM model sample which survive the 7 and 8 TeV LHC. We note that our projections for the sensitivity of the 14 TeV LHC to the pMSSM models under consideration include only the search channels expected to be the most powerful.
searches, ensuring that each model is in agreement with the observed Higgs mass within 3 GeV, corresponding to the theoretical error on the prediction of the Higgs mass in Super-symmetry [28]. These models have the following characteristics: half of these models (i.e., 500 models) are predicted to be detectable at the 14 TeV LHC with 300 fb$^{-1}$, while the other half are expected to remain viable (i.e., unobserved) even after 3000 fb$^{-1}$ at 14 TeV as described in [27]. Since the CP-violating phases have minimal impact on the observability of models at the LHC, we choose to consider the effect of incorporating CP-violating phases to pMSSM models for which the LHC phenomenology has already been studied.

We now extend the 19-dimensional parameter space of each of these 1000 pMSSM models to include the phases present in the MSSM that are consistent with the pMSSM flavor structure. As discussed above, generically, six combinations of MSSM parameters can take on physical CP-violating phases; these combinations can be chosen to be $M_1 \mu B_\mu^*$, $M_2 \mu B_\mu^*$, $M_3 \mu B_\mu^*$, $A_tM_3^*$, $A_bM_3^*$, and $A_\tau M_3^*$. We choose to work in a basis where $M_3$ and $B_\mu$ are real, so that the parameters with physical phases are $M_1$, $M_2$, $\mu$, $A_t$, $A_b$ and $A_\tau$. For each of the 1000 models we perform a random scan over these six physical phases, generating an additional 1000 models in each case, resulting in a total of $10^6$ models with CP-violating phases. The scan over the phases incorporates a log-uniform distribution over the range $10^{-6}\pi/2$ to $\pi/2$, with a random sign, as summarized in table 1. This choice facilitates the study of a wider range of possible phases than that obtainable with a simple uniform scan distribution. The overall sign of the parameters corresponding to these phases is fixed in the pMSSM. The choice of a $\pi/2$ upper bound on the magnitude of the phase preserves the sign of the real part of the corresponding parameters. To restate: the result of this scan yields a total of 1 million models with non-zero CP-violating phases available for study.

In what follows, we will refer to several different categories of models within our $10^6$ model sample of the phase-extended pMSSM. For clarity and ease of reference, the various model sub-categories considered in this work are summarized in Table 2. The original 1000 pMSSM models without phases are denoted as set A, divided into the half that is observable at the 14 TeV LHC (A1), and the half that is expected to evade the 14 TeV SUSY searches (A2). The full set of $10^6$ models in the phase-extended pMSSM is designated as set B. B1(B2) refers to the phase-extended models that are derived from the zero-phase pMSSM A1(A2) models that are observable (not observable) at the 14 TeV LHC, as detailed above.

In this study, we employ the SUSY_FLAVOR v2.10 code [29,31] to calculate a comprehensive set of low-energy observables for the $10^6$ models in set B. We performed an extensive number of analyses to verify the consistency of the output of the SUSY_FLAVOR v2.10 code. The full list of processes we study is given in Table 3 along with the SM prediction for each observable as calculated by SUSY_FLAVOR, the current experimental result, and the expected future experimental plus theory uncertainties or bounds as applicable. We note that in many cases, the expected future measurements will provide a vast improvement over current sensitivity. The values of the input parameters, and their sources, that are required for the SUSY_FLAVOR computations are listed in Table 4. Where they overlap, we took the input parameters to be identical to those used to generate the corresponding pMSSM models. The remaining parameters were chosen according to recent measurements, global data fits, or lattice calculations.

The observables listed in Table 3 are the most constraining flavor and CP-violating processes computed by SUSY_FLAVOR. While the focus of this work is on CP-violating observ-
Table 1: Scan ranges for the 25 parameters of the phase-extended pMSSM with a neutralino LSP. Mass parameters and $\tan \beta$ are scanned with flat priors, while the phases are scanned with log priors.

| Set name | # of models | Description                                      |
|----------|-------------|--------------------------------------------------|
| A        | 1000        | Full pMSSM model set without phases              |
| A1       | 500         | pMSSM models to which LHC-14 will be sensitive   |
| A2       | 500         | pMSSM models which evade LHC-14 constraints      |
| B        | $10^6$      | Full model set A extended to include random phases|
| B1       | $5 \times 10^5$ | A1 with random phases                      |
| B2       | $5 \times 10^5$ | A2 with random phases                      |
| C        | 155,474     | Number from set B allowed by current flavor & CP constraints |
| C1       | 75,216      | Number from B1 allowed by current flavor & CP constraints |
| C2       | 80,258      | Number from B2 allowed by current flavor & CP constraints |
| D        | 3708        | Number from set B allowed after future flavor & CP null results |
| D1       | 1714        | Number from B1 allowed after future flavor & CP null results |
| D2       | 1994        | Number from B2 allowed after future flavor & CP null results |

Table 2: List of model categories referred to in the text along with the number of models in the category and a brief description. For further details, see the text.
ables, the addition of CP-violating phases can also modify the pMSSM predictions for flavor changing, CP-conserving transitions due to the presence of $\phi$-dependent terms in the overall rates. Furthermore, only some of the low-energy constraints in Table 3 have been applied during the generation of the pMSSM models in previous studies [26]. The constraints from these processes offer a more complete picture of the current low-energy restrictions on the pMSSM.

Beginning with the original set $B$ of $10^6$ models, we first determine the subset of these models that satisfy all of the existing flavor and CP constraints: We call this set $C$. Similarly, beginning with the $B_1(B_2)$ set we derive those denoted as $C_1(C_2)$. Finally, we also consider the subset of $B$ models that are expected to survive the future flavor and CP constraints according to our study below, and refer to that subset as set $D$ with analogously defined $D_1$ and $D_2$ subsets.

In the following analysis, we will mainly investigate model set $C$, containing the 155,474 models for which the predicted values of the observables in Table 3 are below the current 90% CL limits or within $2\sigma$ of the observed values for measured quantities. Some models, particularly those with large values of $\tan \beta$, can generate significant corrections to the CKM matrix elements, as well as Yukawa couplings [15]. In these cases, $\tan \beta$ enhancements compensate for loop factor suppressions and can lead to large loop contributions with diminished perturbative control without, e.g., resummation. Thus we enforce a cut of 40% on the size of the maximal correction to the CKM matrix elements or the Yukawa couplings. The most constraining observables at this stage are $d_e$, $\text{Br}(B_s \to \mu\mu)$, and $\text{Br}(B \to s\gamma)$.

We will also consider the models denoted by $D$, $D_1$, and $D_2$ that are expected to remain viable after future flavor experiments are performed assuming the central measured value agrees with the SM prediction. The $D$ model sets are comprised of 3708, 1994, and 1714 models, respectively, where $D_1$ and $D_2$ represent the sets corresponding to the LHC discovery criteria described above. In this study, we employ the anticipated future experimental uncertainties given in [1].

For several observables, the improvement in future sensitivity is dominated by the expected reduction in the error associated with the theoretical calculation of the value for the process. To estimate the theoretical errors, we include the uncertainties from both the input parameters and those due to lattice calculations and/or higher order terms in the expansion employed in the calculation. While the present uncertainties on the observables studied in this work are well documented in the literature, we estimated the projected future uncertainties independently.

Specifically, we estimate the future theoretical uncertainties on an observable $O$ as follows. In general, the calculation of $O$ can depend on model parameters $\alpha_i$ which are expected to be determined with uncertainties $\sigma(\alpha_i)$ with updated experimental input or improved

\footnote{We do not apply the experimental constraint on $(g - 2)_\mu$ at this stage as it lies 3.4$\sigma$ deviation from the SM prediction. In the following analysis, we will consider the possibility that future measurements observe either the SM prediction, or the current central value, with increased precision.}
| Observable | SM | Experiment* | Future Thy. + Exp. bound/uncertainty |

Table 3: The complete set of observables studied in this work. All processes are computed using SUSY FLAVOR v2.10.

Calculations. The most important parameters $\alpha_i$ for our analysis are the CKM angle $|V_{ub}|$ and the CKM phase $\delta$, although we include all the parameters listed in Table 4. The uncertainty in $O$ due to the corresponding error in $\alpha_i$ can be estimated as

$$\sigma_i(O) = \frac{\partial O}{\partial \alpha_i} \sigma(\alpha_i).$$
The computation of $O$ can also have an uncertainty due to the approximations used to derive the amplitude for $O$, which we denote by $\sigma_{th}(O)$. Then the total uncertainty $\sigma(O)$ for an observable can be determined by adding $\sigma_i(O)$ and $\sigma_{th}(O)$ in quadrature as

$$\sigma^2(O) = \sigma^2_{th}(O) + \sum_i \sigma^2_i(O).$$

Strictly speaking, the theoretical uncertainty is model dependent, however we assume the SM and leading expressions for $O$ in our estimations. The uncertainties estimated in this manner are more conservative than those quoted in other studies, but generally agree well (see Table 3). In order to obtain projections for future uncertainties, we assume the improvements in the model parameters as outlined in [1], while taking $\sigma_{th}(O)$ to remain unchanged. The resulting error projections are shown in the rightmost column of Table 3.

It is worth noting already at this point that the relative sizes of the two subsets C1 and C2, as well as D1 and D2, are comparable. This observed similarity is an indicator of a high degree of complementarity between the direct searches at the LHC and low-energy probes of the MSSM. A strong constraint from the LHC only biases the low-energy bounds by roughly $\sim 10\%$.

### 3 Numerical Results

We now characterize the model sets C and D, the pMSSM models with CP phases satisfying the current and expected future constraints, respectively, from low-energy observables.

We begin our survey with an overview of the values of the phases in the CP-violating pMSSM. The first five panels of Figure 1 contain histograms of the values of the CP phases $\phi_{1,2,\mu,t,b}$ after applying the current (blue histogram, model set C) and future (green histogram, model set D) constraints on the observables in Table 3. In showing the expected future constraints, we once again emphasize our assumption that experimental measurements will obtain the SM predictions given in Table 3. These figures demonstrate the high sensitivity of future flavor experiments to the phases $\phi_1$, $\phi_2$, $\phi_\mu$ and $\phi_t$. Null results from future experiments would require $\phi_2$ and $\phi_\mu$ to be small, $O(10^{-2})$ or less, while weaker limits of $O(10^{-1})$ would be placed on $\phi_1$ and $\phi_t$. Interestingly, $O(1)$ values of $\phi_b$ would remain essentially unconstrained. We note that $\phi_\tau$ (not shown) also remains unconstrained.

Figure 1 displays a two-dimensional density histogram of the phases $\phi_2$ and $\phi_\mu$ for the models that pass current constraints (model set C) and illustrates interesting correlations. Note that there is a region with $\phi_2 \approx \phi_\mu$ where $O(1)$ values of both phases are allowed. This corresponds to the case where the most significant effective phase contributing to the EDMs is effectively zero, due to a cancellation among gaugino exchange diagrams [69]. Due to this cancellation, models with large and nearly equal phases $\phi_2$ and $\phi_\mu$ survive the EDM bounds. These models are, however, tuned in the sense that they are delicately sensitive to the degree of cancellation between these phases.

The observables that are most sensitive to CP-violating effects are the electron and neutron EDMs, as well as $\sin 2\beta$ and $\epsilon_K$. The upper four panels of Figure 2 show histograms of these quantities, demonstrating the potential of individual experiments to constrain these observables or detect new physics arising from SUSY. In each panel, the upper histogram
corresponds to models that have passed all the current constraints (blue, model set C), while the lower histogram (green) is obtained by applying anticipated future constraints from all observables except for the one under study. The expected future limit on the EDMs is represented by the vertical lines. Here, we see the well-known feature that future EDM constraints will be very important in probing supersymmetric CP phases. We note, however, that the expected future measurements for $\sin 2\beta$ and $\epsilon_K$ lie outside the ranges shown in the histograms, indicating that improved measurements of these quantities will not further constrain these models. We observe that there is a large correlation between $\sin 2\beta$ and the EDMs, as the models passing future constraints (dominated by EDM limits) cluster around the SM expectations for $\sin 2\beta$.

Table 4: Values of Standard Model, lattice, and observational quantities we employ with 
SUSY_FLAVOR v2.10.
Figure 1: (a)-(e): Distributions of the CP-violating phases $\phi_{1,2,\mu,t,b}$ added to the pMSSM in model sets C (blue) and D (green). (f): Model densities of values for the phases $\phi_2$ and $\phi_\mu$ in model set C. The shading ranges from light blue to dark blue with the darkness being logarithmic in the number of models in the bin. White bins contain no models. The model sets are defined in Table 2.
Figure 2: (a)-(d): Expected constraints from future low-energy experiments on the pMSSM models with CP violation. In each panel, the top histogram shows models after applying current constraints (blue, model set C), while the bottom histogram (green) represents the remaining models after applying all future constraints except for the observable under study. This illustrates the exclusive ability of that observable to probe the model parameter space. Where possible, the anticipated future limit on the observable is indicated by a vertical or horizontal line. (e)-(f): Model densities for the observables in model set C. The shading is as in Figure 1(f).
If future EDM experiments continue to obtain null results, a non-SM measurement of \( \sin 2\beta \) would thus pose an intriguing challenge to the CP-violating pMSSM. On the other hand, we see that \( \epsilon_K \) is not particularly sensitive to the gaugino phases and is therefore poorly correlated with the other CP-violating observables. A relatively large deviation from the SM in \( \epsilon_K \) would still be possible, even if future EDM searches are null. The lower two panels of Figure 2 display two-dimensional histograms of these observables for models in agreement with the current experimental constraints (model set C). The lines in figure 2e correspond to the anticipated future limits listed in Table 3. These figures serve to further illustrate the correlations among CP-violating observables. We see that the electron and neutron EDMs are strongly aligned as expected, while there is no correlation between \( \sin 2\beta \) and \( \epsilon_K \), due to the latter’s lack of sensitivity to the gaugino phases.

To further explore the constraints placed on the phases, Figure 3 contains two-dimensional histograms showing the neutrino and electrons EDMs paired with \( \phi_1, \phi_2, \) or \( \phi_\mu \) for models that are allowed by current constraints (model set C). The anticipated future EDM search reach corresponds to the horizontal line. The electron EDM provides a particularly strong constraint on large values of all three phases. Most models with phases larger than \( \sim 10^{-1} \) are already excluded, and the parameter space will be further explored by an order of magnitude in the values of the phases to roughly \( 10^{-2} \). However, some room remains for rather large values of the phases due to possible cancellations of the contributions arising from \( \phi_\mu \) and \( \phi_2 \) as described above.

Low-energy observables that are sensitive to the \( A \)-term phases \( \phi_t, \phi_b, \) and \( \phi_\tau \) must involve flavor-violating couplings. The most sensitive such observables that are incorporated in SUSY\_FLAVOR are \( \sin 2\beta \) and \( \epsilon_K \). The dependence on \( \phi_b \) and \( \phi_\tau \) in these observables is extremely weak; \( \phi_b \) contributions are typically suppressed by \( m_b \) (except possibly at large \( \tan \beta \)), while \( \phi_\tau \) would contribute only to \( \tau \) flavor violating processes or poorly measured observables such as the \( \tau \) EDM. The impact of \( \phi_t \) on the electron and neutron EDMs, as well as on \( \sin 2\beta \) and \( \epsilon_K \), is shown in Figure 4. Unlike the structure illustrated in Figure 3, we see that there is no correlation between most of these quantities and the phase \( \phi_t \). We note that a mild constraint on models with large \( \phi_t \) is possible from the neutron EDM, however improving the precision on \( \sin 2\beta \) and \( \epsilon_K \) does not bound these phases.

Next, we consider the correlation between low-energy observables and direct LHC searches for Supersymmetry in order to determine the degree of complementarity between the two approaches for probing Supersymmetry. To do so, we consider models that are expected to evade Jets+MET and stop-squark searches at the LHC with 3000 fb\(^{-1}\) of integrated luminosity (extracted from model sets C and D). Figure 5 shows a comparison of the impact of low-energy experiments to that of direct LHC searches in exploring the pMSSM models with CP phases. In all cases, we see that the shape of the distribution remains essentially unchanged, and only the number of viable models is affected by the LHC searches. Hence, the ability of the current and future measurements of low-energy observables to constrain models is observed to be independent of the the discovery reach of the LHC. These results indicate a high degree of complementarity between the low-energy CP violation experiments and the direct SUSY searches at the LHC as probes of the MSSM.
Figure 3: Model densities for the electron and neutron EDMs as a function of the phases $\phi_1$, $\phi_2$ and $\phi_\mu$ in model set C. The shading is as in Figure 1f. The lines indicate the future expected EDM reaches.
Figure 4: Model densities for the electron and neutron EDMs, $\sin 2\beta$ and $\epsilon_K$ as a function of the phase $\phi_t$ in model set C. The shading is as in Figure 1(f). The horizontal lines in the top panels indicate expected future EDM limits. The expected future constraints on $\sin 2\beta$ and $\epsilon_K$ lie outside the ranges of the lower panels.

Although the main thrust of this work is to study CP-violating observables, flavor-changing CP-conserving observables, as well as the anomalous magnetic moment of the muon, are also sensitive to the presence of CP-violating phases. We therefore next examine the most sensitive flavor-violating, CP-conserving observables to study their sensitivity to the pMSSM phases. In Figures 6 and 7 we compare the predicted rates of various processes in the original CP-conserving pMSSM (model set A on the x-axis) with their CP-violating counterparts (model set C on the y-axis). While we see a strong correlation between the two model sets in the CP-conserving processes, it is clear that the presence of phases lead to some interesting effects.
Figure 5: Complementarity between the low-energy experiments and the direct SUSY searches at the LHC. The left panels are identical to Figures 1(a), 2(a), and 2(c), respectively. The right panels are the corresponding figures including only those models that are expected to evade the leading 14 TeV LHC direct SUSY searches with 3000 fb$^{-1}$ of integrated luminosity. Note the difference in the scale of the vertical axis between the left and right panels.
Figure 6: Comparison of several flavor-changing, CP-conserving $B$ physics observables in the original pMSSM models without CP violation (model set A on the horizontal axes) and the corresponding models with randomly selected phases (model set C on the vertical axes). The lines indicate future expected measurements on the various observables. The shading is as in Figure 1(f).
In particular, $\text{Br}(B_{s,d} \rightarrow \mu^+\mu^-)$ and $\text{Br}(B \rightarrow X_s\gamma)$ all experience non-trivial contributions from supersymmetric CP phases and future experiments should have a significant sensitivity to these contributions. It is particularly noteworthy that while some of the CP-conserving pMSSM models are expected to be probed by future measurements of $\text{Br}(B \rightarrow X_s\gamma)$ and $\text{Br}(B_s \rightarrow \mu^+\mu^-)$, introducing CP-violating phases has the potential to bring predictions for these processes back into agreement with the SM rates.

In particular, the ratio of $\text{Br}(B_s \rightarrow \mu^+\mu^-)$ in the MSSM to that in the SM can be written to a very good approximation in the following way,

$$\frac{\text{Br}(B_s \rightarrow \mu^+\mu^-)|_{\text{MSSM}}}{\text{Br}(B_s \rightarrow \mu^+\mu^-)|_{\text{SM}}} = |X|^2 + |1 + X|^2,$$

(3)

where $X$ is the new contribution from the supersymmetric partners. Writing $X$ as $X = \pm xe^{i\theta}$, Eq. (3) reduces to (here $x$ is taken to be positive by convention and, barring large cancellation, must satisfy $x << 1$ to be consistent with experiment)

$$\frac{\text{Br}(B_s \rightarrow \mu^+\mu^-)|_{\text{MSSM}}}{\text{Br}(B_s \rightarrow \mu^+\mu^-)|_{\text{SM}}} = x^2 + |1 \pm xe^{i\theta}|^2$$

$$= 1 \pm 2x \cos \theta + 2x^2.$$  

(4)

Clearly, for a given value of $x$, the above ratio maximally deviates from unity at $\theta = 0$ and any finite non-zero value of the phase $\theta$ will always push it closer to the SM. Note that the above argument is strictly correct only in the case when the NP amplitude has single contribution. However, even in the presence of multiple contributions, if one of them is the dominant term (which is indeed the case here because the higgsino contribution dominates in most of the parameter space where the constraint from $\text{Br}(B_s \rightarrow \mu^+\mu^-)$ is important) or there are no large cancellations among the various terms, the above argument still holds.

We also see some cases where the addition of CP phases creates a signal in one of these flavor-changing processes that would be detectable by future experiments; this effect, however, is found to be far less common. Note that the rare Kaon processes generally tend not to exhibit these effects and thus are much less sensitive to the presence of CP phases.

We also consider the pMSSM contributions to the anomalous magnetic moment of the muon, $\delta a_{\mu}$. As is well-known, there is presently a claim [47] of an observation of a $> 3\sigma$ deviation in this observable from the current SM prediction. If this deviation were to be confirmed by future experimental results, it would impose a particularly strong constraint on the models considered in this work. Since there remains some controversy surrounding the theoretical calculation, and the measurement itself has yet to be independently confirmed, we have not imposed cuts on $\delta a_{\mu}$ in applying current low-energy constraints to our models (model set C in particular). However, we note that if the current experimental result for $\delta a_{\mu}$ were to be applied at the $2\sigma$ level, only 952 models in model set C would survive. In addition, we have projected the impact of upcoming low energy measurements, assuming that the SM value of $\delta a_{\mu}$ will be confirmed in the future (model set D). It is also interesting to examine the power of a future $\delta a_{\mu}$ measurement which is in agreement with the existing experimental result, e.g., the same central value but with the smaller error bars that may arise from the Muon $g - 2$ collaboration. If the current measurement of $\delta a_{\mu}$ persists but with the errors reduced as projected by the Muon $g - 2$ collaboration, then none of the models in
model set D would remain viable. On the other hand, if the same future result is consistent with the SM, then the measurement of \( \delta a_\mu \) would not provide any exclusionary power beyond the other low energy measurements. In other words, all models that would remain viable from other future low energy flavor and CP-violation experiments are consistent with the SM prediction of \( \delta a_\mu \) within the future anticipated sensitivity of the Muon \( g - 2 \) experiment. These results are shown explicitly in Figure 8, displaying the distribution of \( \delta a_\mu \) in the CP-violating pMSSM model sets consistent with the current and expected future low-energy constraints. Note that the current 2\( \sigma \) lower limit on \( \delta a_\mu \) is \( 11.6 \times 10^{-10} \) since it differs from zero by over 3\( \sigma \).

In Table 5 we compile the fraction of models from set B (CP-violating) that are projected

![Figure 7: Same as Figure 6, but for the anomalous magnetic moment of the muon, as well as rare Kaon processes.](image)
to remain viable after the most sensitive future low-energy measurements are completed, as well as the fraction of models from set A (CP-conserving) for which at least one correlated model in set B is projected to satisfy the constraints. Clearly the neutron and electron EDMs provide the best sensitivity (strongest constraints or larger discovery reach) to the presence of phases in the CP-violating pMSSM, while other observables also provide good sensitivity to these new physics effects. For the case of $(g-2)_\mu$, we assume that future experiment will uphold the current central value. In addition, we show the fraction of models that survive after the combination of all future low-energy measurements (neglecting $(g-2)_\mu$) are performed. This corresponds to only $\sim 0.4\%$ of the original $10^6$ models generated, demonstrating the power of low-energy observables in searching for Supersymmetric CP-violating effects.

4 Discussion and Conclusions

This study explored the complementarity of indirect low-energy probes of the MSSM with those arising from direct SUSY searches at the LHC. The broad suite of future low-energy experiments examined here include flavor-violating decays of the $K$ and $B_{d,s}$ mesons - with and without CP-violating observables, meson mixing, the $g-2$ of the muon, and electric dipole moments. To perform this investigation we employed a previously examined set of
Table 5: The fraction of models in set B (CP-violating) that are projected to remain viable after the most sensitive future low-energy measurements are performed, as well as the fraction of models in set A (CP-conserving) for which at least one correlated model in set B is projected to satisfy constraints. The $(g-2)_\mu$ entries assume that the currently observed central value continues to hold while the corresponding uncertainties shrink as projected in [1]. The $(g-2)_\mu$ constraint is not included in the “All future” row.

| Observable | Fraction of B Models | Fraction of A Models |
|------------|----------------------|----------------------|
| $d_e$      | 0.00645              | 0.746                |
| $d_n$      | 0.0539               | 0.764                |
| Br($B^+ \to X_s\gamma$) | 0.144               | 0.877                |
| Br($B_s \to \mu^+\mu^-$) | 0.148               | 0.888                |
| $(g-2)_\mu$ | 0.000366            | 0.009                |
| All future | 0.00371              | 0.587                |

10^3 CP-conserving pMSSM models (described by specific values of the 19 pMSSM parameters) that satisfy existing experimental constraints, including the value of the observed Higgs boson mass and the direct LHC SUSY searches. For each of these thousand models, we generated 10^3 sets of CP-violating phases, corresponding to those associated with the parameters $M_{1,2,\mu}$ and $A_{t,h,\tau}$, thus yielding a total of 10^6 models that we then employ in our study. This large set of models was then divided into various useful subsets depending upon how a given model is expected to respond to the anticipated 13 TeV LHC direct SUSY searches, as well as both the present and future set of flavor and CP-violating measurements. The sensitivity to the different types of experiments can then be contrasted and compared with these various subsets.

The main result from this study is that we have shown in a quantitative manner that direct SUSY searches at the LHC and measurement of the low-energy observables considered here are almost orthogonal in their sensitivity, and probe the CP-violating pMSSM parameter space in completely different ways. In particular, we find that the low-energy measurements can probe pMSSM models that lie outside of the range of the 13 TeV LHC, even when the CP-violating phases take on modest values. However, we also find regions of parameter space where large phases remain allowed due to a cancellation between the contributions to CP-violating observables, particularly the electron and neutron EDMs. Furthermore, we have also found that the added flexibility derived from the inclusion of the phases can bring the pMSSM predictions closer to the observed experimental results, and Standard Model expectations, for rare processes such as $B_s \to \mu^+\mu^-$ which are seen to be highly restrictive in the absence of such phases.

Of course the true impact of future low-energy observables will be highly correlated with the actual measured values; this is most obvious in the cases of the electron and neutron EDMs and the $(g-2)$ of the muon. In the case of the EDMs, a null measurement will severely constrain the CP violating pMSSM parameter space, especially if the anticipated sensitivity of future measurements is reached. On the other hand, a measurement of $(g-2)$ with the presently observed central value, but with significantly reduced experimental (and
theoretical) errors, would be extremely constraining on this parameter space independently of what is found by the direct SUSY searches at the LHC. However, if the SM prediction for $g - 2$ is obtained with smaller errors, then the impact on the pMSSM parameter space will turn out to be rather modest.

Although constrained by existing searches, the viable SUSY parameter space still remains quite large. Hopefully multiple signals for Supersymmetry will be discovered by a diverse set of experiments during the next few years.
