Abstract

The first metallic glass of Au-Si alloy has been discovered for over half a century, but its atomic structure is still puzzling. Herein, Au₈Si dodecahedrons with local five-fold symmetry are revealed as building blocks in Au-Si metallic glass, and the interconnection modes of Au₈Si dodecahedrons determine the medium-range order. With dimensionality reduction, the surface ordering is attributed to the motif transformation of Au₈Si dodecahedrons into planar Au₅Si pyramids with five-fold symmetry, and thus the self-assembly of Au₅Si pyramids leads to the formation of the ordered Au₂Si monolayer with the lowest energy. Furthermore, the structural similarity analysis is performed to unveil the physical origin of structural characteristics in different dimensions. The amorphism of Au-Si is due to the smooth energy landscape around the global minimum, while the ordered surface structure occurs due to the steep energy landscape.
Introduction

The Au-Si alloy was the first reported metallic glass, which was discovered in 1960 by rapid cooling. Subsequently, bulk metallic glasses (BMGs) have attracted increasing attention due to their fundamental scientific interests and practical applications. Up to now, many computational methods and experimental techniques have been involved to investigate structures of BMGs. However, due to the absence of long-range order it remains challenging to determine atomic structures of BMGs. For example, a combination of experimental measurements and reverse Monte Carlo modelings failed to reproduce the precise packing structures of BMGs at the atomic level without sufficient structural information. Numerous structural models were proposed to improve the understanding of short-range order (SRO) in BMGs over the years, but these models are still difficult to figure out the medium-range order (MRO) of BMGs. To overcome this challenge, the efficient cluster packing on a face-centered cubic lattice was proposed. In 2009, the MRO in BMGs was described by the packing mode of local motifs on a network with fractal dimension \( D_f = 2.32 \), which is smaller than that of crystal \( D_f = 3.0 \) or dodecahedron-quasicrystal \( D_f = 2.72 \), indicating that filling the real space in these amorphous solids by building blocks is impossible. Therefore, unveiling the nature of atomic packing at the MRO scale in BMGs is a long-standing problem.

The Au-Si eutectic alloy has the extremely low eutectic temperature (359 °C) below the melting points of Au (1063 °C) and Si (1412 °C). At the lowest eutectic temperature, it has a composition of \( \text{Au}_{82}\text{Si}_{18} \), which is the key to the catalytic growth of silicon nanowires because Si atoms maintain relatively high mobility at low temperatures. In recent years, although some theoretical studies reported possible alloy structures of Au-Si, the local ordering of Au-Si BMG is still lacking. Interestingly, two-dimensional (2D) crystallization was observed at the surface of Au-Si metallic glass, which has been experimentally confirmed to be an ordered rectangular structure with the proposed Si-Si bond on the surface. Shpyrko and co-workers claimed that the Au-Si surface ordering was induced
by surface-induced freezing, but the ordered prefreezing surface will only appear near the transition temperature rather than a wide range of temperatures, inconsistent with the case of Au-Si. Moreover, density functional theory (DFT) calculations proved that the Si-Si bond is energetically unfavorable in the Au-Si alloy, implying the inconsistency in literature. This ordered surface plays a key role in crystal growth and solidification, but the atomic arrangement is still unclear. Therefore, uncovering the atomic structures of surface crystallization and Au-Si alloy will be beneficial for understanding exotic properties of Au-Si metallic glass.

In this article, *ab initio* molecular dynamics (AIMD) simulations were performed to investigate the bonding features of Au-Si in the undercooled state. The partial distribution function and coordination number analysis were employed to explore the SRO of liquid Au-Si alloy, and a set of Au$_8$Si dodecahedrons with local five-fold symmetry are the most energetically favorable motifs. The connection modes of different Au$_8$Si motifs with similar energies are substantial to reconstruct the Au-Si eutectic alloy, subtly affecting the structural stability of Au-Si. With dimensionality reduction, the basic building motifs, i.e., Au$_8$Si dodecahedrons, are reduced to be Au$_5$Si pyramids, which are Si-centered pentagons with five-fold symmetry. This phenomenon is confirmed by a systematic investigation of surface structures on the Au-Si alloy. Moreover, a 2D ordered Au$_2$Si monolayer composed of Au$_5$Si pyramids is found, which is more energetically favorable compared with all the earlier proposed surface structures. Notably, the simulated scanning tunneling microscope (STM) images are in much better agreement with the experimental results. Furthermore, the remarkable difference of structural similarity between the Au-Si bulk and surface structures is uncovered, providing insights into understanding why the bulk structure is a metallic glass while the surface alloy exhibits long-range order.
Results and discussion

To extract the inherent local SRO of Au$_{82}$Si$_{18}$, the initial configurations were constructed based on the Au bulk in thermal equilibrium, where a certain number of Au atoms were randomly replaced with Si atoms. To avoid the systematic error, 100 configurations were used to produce structural information, for instance, the average coordination numbers and the partial pair-correlation functions (see the details in the section of computational methods in the Supplemental Material (SM)). As shown in Fig. 1(a), the partial pair-correlation functions $g_{ij}(r)$ of Au$_{82}$Si$_{18}$ were obtained after the undercooling process, where the simulation temperatures were quickly reduced to 300 K from 2000 K with a large cooling rate of $1 \times 10^{11}$ K/s. The first peak of Au-Si is located at around 2.45 Å, suggesting the intensive mixing between Au and Si atoms. The first broad peak of Si-Si appears around 4 Å, showing that Si atoms are prohibited from being bonded together and surrounded by Au atoms. This phenomenon implies the existence of close packing that holds Si atoms like “solute” atoms in the center of polyhedrons. The coordination number (CN) analysis reveals that Au$_8$Si polyhedrons are the most frequent motifs in the Au-Si BMG, where the ratio reaches up to 79%, as shown in Fig. 1(b). It is worth noting that the frequent Au$_8$Si motifs have local five-fold symmetry in Fig. 1(c), which is responsible for the SRO. As a result, we can infer that the atomic structure of the Au-Si alloy is the self-assembly of Au$_8$Si dodecahedrons by connecting each other in a close-packed manner.

To determine the MRO in Au-Si, we need to reveal the origin of its structural stability, where the building blocks and connection rules are crucial to identify the local atomic ordering. According to the bonding features we obtained in Figs. 1(a), 1(b), we constructed a series of Au-Si configurations, which contain Au$_n$Si ($n = 6 – 10$) polyhedrons in a corner-sharing or edge-sharing mode, to explore stable structures of Au-Si alloy. As shown in Fig. 2(a), the Au$_4$Si structure has the lowest formation energy, which is in excellent agreement with the eutectic point of the Au-Si phase diagram. Particularly, two most stable structures with almost the same energy have been found, which are both comprised of Au$_8$Si
Figure 1: (a) The pair-correlation functions of Au$_{82}$Si$_{18}$ BMG at room temperature. For clarification, the Si-Si and Au-Si partials are shifted by 5 and 10, respectively. Motifs in body-centered cubic (see Fig. 2(b)) and hexagonal close-packed (see Fig. 2(c)) structures. Moreover, we find that these two Au$_8$Si motifs can be combined together to form relatively stable structures with a larger number of atoms (see Fig. 2(d)), indicating that the connection modes are not dominant for the structural stability of Au-Si compared to the local atomic ordering. Therefore, the MRO at the atomic level is ascribed to the interconnection modes of Au$_8$Si motifs. It is worth noting that the formation energy distribution at Au concentration of 0.8 is very close, implying a flat energy landscape and the origin of

formation mechanism in Au-Si.$^{[27]}$

The Au$_8$Si dodecahedrons with local five-fold symmetry are found to be the SRO in Au-
Si, but with dimensionality reduction the SRO of surface structures still leaves unknown. The surface crystallization of Au-Si BMG was observed in the last decade, however, the origin and atomic structure of the surface ordering are still in debate. We carried out AIMD simulations at 650 K to study the Si content in a roughly 25 Å-thick Au$_{82}$Si$_{18}$ slab with six layers, and five different slab models were considered to reduce systematic errors. During AIMD simulations Si atoms migrate to the surface from the central region, resulting in the higher concentration of Si atoms (around 42%) in the surface region, as shown in Fig. 3(a). Therefore, our results agree with the fact that Si atoms prefer the surface segregation in experiments, and the surface structure of Au-Si alloy is the mixture of Au and Si atoms.

Interestingly, this ordered rectangular surface structure with the same lattice parameters has also been experimentally observed by depositing Si atoms on the Au(111) substrate. Therefore, it is possible to search for the stable Au-Si surface structure on the Au(111) substrate. At the initial stage of the nucleation process, only one Si atom was introduced to react with the Au(111) substrate. The Au$_n$Si ($n = 3 \cdots 7$) clusters with various coordination numbers for Si on Au(111) are shown in Fig. 3(b). It is apparent that the Au$_5$Si cluster with five-fold symmetry has the lowest formation energy, indicating that the Au$_5$Si pyramid is an energetically favorable motif in the Au-Si system.

To efficiently search for the possible structure of 2D Au-Si alloy, surface structure generation methods were employed to fertilize the structure database of Au-Si monolayers. We generated non-duplicated 2D Au-Si surface structures with various atomic ratios and distributions by the package of Structures of Alloy Generation And Recognition (SAGAR) and the crystal prediction algorithm RG2 based on space group theory and graph theory. To consider the lattice mismatch between monolayers and Au(111), we constructed various supercells. High-throughput first-principles calculations were performed to determine the possible surface structure on Au(111). As shown in Fig. S1 of the SM, our results point out that Au-Si monolayers with Au$_5$Si pyramids are rather stable compared with those monolayers without Au$_5$Si pyramids, indicating that the Au$_5$Si motif with five-fold symmetry is

the key SRO in surface structures of Au-Si.

Particularly, the most stable Au-Si monolayer on Au(111) is $\text{Au}_2\text{Si}$ comprised of pen-
tagons and rhombuses, and the relaxed Au$_2$Si monolayer on Au(111) are shown in Fig. 3(c). Intriguingly, the lattice parameters of the most stable Au$_2$Si monolayer are $a = 9.451$ Å and $b = 7.515$ Å, which are in excellent agreement with previous experiment results. Si atoms are at a lower height than Au atoms in the Au-Si monolayer, implying that each rhombus contains four Au atoms in the topmost layer and Si atoms are separated by these Au$_4$ rhombuses. According to the experimental and simulated STM images shown in Fig. 3(d), the bright protrusions correspond to the Au$_4$ rhombuses. There are two types of protrusions in the Au$_2$Si monolayer that are rotated with respect to each other as highlighted by the ellipses, corresponding to the two types of Au atoms with different heights in Fig. 3(c). The Au$_3$Si pyramids reflect dark pores in the STM image because the Si atoms are at a relatively low height. Therefore, we conclude that the Au$_2$Si monolayer forms by depositing Si atoms on the Au(111) substrate.

To further confirm the existence of the ordered Au$_2$Si monolayer at the surface of Au$_{82}$Si$_{18}$ BMG, various Au-Si overlayers were deposited on the five slab models mentioned above in Fig. 3(a). The calculated formation energies on these five substrates are shown in Fig. S2 of the SM, where the Au$_2$Si overlayer exhibits robust stability on different substrates, while other overlayers are less stable. This is strong evidence that the Au$_2$Si monolayer is the pretty stable ordered surface structure of Au-Si BMG.

The Au-Si BMG displays diverse structural characteristics in different dimensions, which is attributed to unusual Au-Si bonding properties and dimensionality reduction. To unveil the deep physical nature of the phenomenon, the energy landscape of the Au-Si system is comprehensively investigated to uncover the origin of the distinction between bulk and surface. If the global minimum is surrounded by numerous local minima, namely, lots of low energy saddle points are around the ground state structure, this system is a glassy system, otherwise, it belongs to a structure seeker system. For instance, the carbon and boron nitride systems can be clearly identified as structure seekers while the large boron cluster systems are glassy.9
To define the distance between any two structures, we employed the Smooth Overlap of Atomic Positions (SOAP) descriptor to encode regions of atomic geometries by using local expansion of a gaussian smeared atomic density. The bulk Au-Si alloy and surface structures were generated by SAGAR and RG2 algorithm as mentioned above. We chose several low-energy Au-Si structures to perform the distance-energy analysis in 2D and three-dimensional (3D) systems as shown in Fig. 4(a). For 2D surface structures, the formation energy increases rather quickly with configuration coordinate, and the saddle
points are relatively far away from each other according to the configuration coordinate compared to the case of 3D bulk structures. In the bulk case, the blue color in Fig. 1(b) represents that the distances among the low energy structures are rather small, indicating that there is a low energy barrier between two local minima. This feature leads to the fact that it is difficult to form any ordered bulk Au-Si alloy during the rapid cooling process, which is confirmed by molecular dynamics simulations in Au-Si BMG. However, the image of the Au-Si surface structure (see Fig. 1(c)) is almost filled with red color, implying that distances are much larger between low and high energy structures. Therefore, the long-range ordering can easily appear in surface structures.

In summary, we have uncovered the local ordering of Au-Si, where the Au₈Si motifs with local five-fold symmetry are the basic building blocks and the different connection modes reveal the MRO. With dimensionality reduction, the SRO of Au-Si surface structure has been transformed into Au₅Si pyramids with five-fold symmetry. We have concluded that the Au₂Si monolayer composed of Au₅Si pyramids is the surface structure observed in experiments, due to the lowest formation energy and excellent agreement with STM images. Employing the structural similarity matrix based on the SOAP descriptor to metricize the distance among Au-Si structures, we have shown that there is a smooth energy landscape with dense local minima for the Au-Si bulk, while the energy landscape of Au-Si surface structures is relatively steep around the ground state. Our work not only supplies a structure search method to determine the Au-Si structures in different dimensions but also expounds on the intrinsic origin of the order-disorder transition in Au-Si alloy from 2D to 3D, which may pave a promising avenue to explore the novel properties in other metallic glasses.
