Abstract

Extramedullary hematopoiesis (EMH) is a rare cause of adrenal mass. We present a 44-year-old woman who has thalassaemia intermedia, referred to Endocrinology clinic for huge adrenal mass. Along with a paraspinal lesion discovered in this patient, the leading diagnosis was EMH. The patient was treated with hypertransfusion and hydroxyurea, which led to a reduction in the size of the right adrenal mass and paraspinal mass.

This case highlights the challenges in managing this rare condition. Although EMH is a rare cause of adrenal mass, the diagnosis must be considered in any patient with a history of a congenital hemolytic disorder, to avoid unnecessary surgical procedures.

Key words: adrenal mass, adrenal incidentaloma, extramedullary hematopoiesis, thalassaemia, congenital haemolytic disorder

INTRODUCTION

Thalassaemia is one of the most common autosomal recessive disorders and is highly prevalent in countries within the tropical belt, including Malaysia.1,2 In Malaysia, thalassaemia is the most common inherited blood disorder.3 Extramedullary hematopoiesis (EMH) is a well-documented manifestation of thalassemia, as well as other severe disorders of hematopoiesis.4 The usual sites involved include the liver, spleen and paraspinal regions. The adrenal as a site of extramedullary haematopoiesis is rarely seen.5

Herein, we report a rare case of huge right adrenal mass in a 44-year-old woman who has inherited hemoglobinopathy.

CASE

A 44-year-old female with underlying essential hypertension since 2016, was diagnosed to have thalassaemia intermedia since 2002 at the age of 27 years old. She required infrequent blood transfusion until 2017.

Her DNA analysis of alpha and beta globin genes detected the presence of a single alpha gene deletion, together with compound heterozygous state for β-thalassaemia and Siriraj βγδβ-thalassaemia. This patient has a vague abdominal mass since 2016. The ultrasound of hepatobiliary system showed a right liver lobe mass.

A computed tomography of the abdomen was performed which revealed incidental finding of a right adrenal mass. The patient was then referred to the Endocrinology clinic for further workup of the adrenal mass.

Otherwise, the patient did not have symptoms of anaemia. She did not experience excessive weight gain, easy bruising or fracture. She denied headache, palpitation, flushing, abdominal pain, tremor or anxiety. Her menses were regular with no history of menorrhagia or dysmenorrhea. She had no history of surgery. Her younger brother was diagnosed to have thalassaemia intermedia and was on regular blood transfusion. She is a housewife. She neither smokes nor drinks alcohol.

On physical examination, she had mild pallor and jaundice but no cushingoid feature. Her weight was 56.1 kg, height was 158 cm, with BMI of 22.5 kg/m². Abdominal examination showed fullness of the abdominal right upper quadrant with large palpable firm mass, and huge splenomegaly extending interfrenomedially to umbilical level. Cardiovascular and respiratory examinations were unremarkable. There was no neurological deficit.

Blood investigation showed chronic microcytic hypochromic anaemia with hemoglobin level of 7.6–9.9 g/dL on different occasions. Other blood parameters are shown in Table 1. Her adrenal hormone assessment was normal (Table 2).
Computed tomography (CT) of the thorax, abdomen, pelvis, including adrenal protocol done in year 2018, showed a large heterogenous enhancing mass with necrotic area arising from the right adrenal gland, measuring 11.0x9.8x14.8 cm (Figure 1), with average attenuation of 40 HU from non-contrast CT, absolute and relative washout were 24% and 12% respectively. The adrenal mass was indenting on the segment VI of the liver and right kidney, with the right kidney displaced inferiorly. The left adrenal gland was normal. The radiologist concluded that the right adrenal mass was indeterminate and in view of the patient's history of thalassaemia, the adrenal lesion likely represented adrenal extramedullary hematopoiesis. Besides this, the paraspinal mass also noted from the CT scan was in keeping with extramedullary hematopoiesis (Figures 2 and 3).

A multidisciplinary discussion was held between endocrinologists and haematologists and they concluded that the patient was not suitable for operation owing to high bleeding risk. Subsequently, she was given hypertransfusion, with the aim of achieving a level more than 12 g/dL. Furthermore, this patient was started on iron chelating agent due to iron overload. Hydroxyurea was commenced as part of the treatment for extramedullary haematopoiesis. Computed tomography scan of the abdomen was repeated in year 2020 and showed size reduction of the right adrenal mass and paraspinal mass (Figure 4).

**DISCUSSION**

The proportion of adrenal mass discovered incidentally on imaging studies was estimated to be 1–5% of all

---

**Table 1. Initial blood investigations**

| Investigation          | Value   | Reference value |
|------------------------|---------|-----------------|
| Total bilirubin        | 54      | 5-21 µmol/L     |
| Alanine transaminase   | 21      | 10-49 U/L       |
| Alkaline phosphatase   | 52      | 46-116 U/L      |
| Albumin                | 44      | 32-48 g/L       |
| Sodium                 | 141     | 136-145 mmol/L  |
| Potassium              | 3.5     | 3.5 to 5.1 mmol/L |
| Creatinine             | 45 µmol/L |                |
| Serum ferritin         | 1313.65 | 10-291 µg/L     |
| Tumor marker           | CA125: 5.1 | CA 125: <35 U/mL |
|                        | CA19-9: 7.7 | CA19-9: <37 U/mL |
| Alpha fetoprotein      | < 1.1   | < 6.7 IU/mL     |
| CEA                    | 3.3     | CEA: <5 µg/L    |
| TSH                    | 2.96    | 0.55 to 4.78 mIU/L |
| Free T4                | 15.7    | 11.5-22.7 pmol/L |

**Table 2. Adrenal hormonal investigations**

| Investigation                   | Value                        | Reference value            |
|---------------------------------|------------------------------|-----------------------------|
| Cortisol                        | 212.7                        | 119-618 nmol/L              |
| ACTH level                      | 3.7                          | <10.2 pmol/L                |
| Serum Dehydroepiandrosterone   | <0.41                        | 0.95-11.7 µmol/L            |
| Testosterone level              | <0.1                         | 0.30-1.7 nmol/L             |
| 24 hour - urine catecholamine   | Dopamine: 510ug/day (mild elevation of dopamine, not diagnostic of pheochromocytoma) | Dopamine: 64-400 ug/day |
|                                 | Epinephrine: not detected    |                             |
|                                 | Norepinephrine: 58.8 ug/day  |                             |
| Overnight dexamethasone suppression test | 16.8 (cortisol suppressed) | <50 nmol/L                  |
| Renin                           | Renin: 11.1                  | Renin (mU/L):               |
|                                 | Aldosterone: <103            | Supine: 4.2 -59.7           |

|                                 | Upright: 102.5-1196.6        |                             |
abdominal CT scans performed. In our case, the patient was referred to endocrinology team for an adrenal incidentaloma. Given the imaging findings of the incidental adrenal lesion and paraspinal lesion discovered in a patient with thalassaemia, the leading diagnosis is extramedullary hematopoiesis.

This patient did not have underlying primary malignancy to suggest metastatic disease as one of the differential diagnoses. Adrenal adenoma is unlikely in this case, nor is it associated with paraspinal lesion. The adrenal lesion is huge with its attenuation of 40 HU from the non-contrast CT. Although the adrenal lesion in this patient is huge, other CT features are not suggestive of adrenocortical carcinoma, where irregular shaped, stellar central hypodensity and capsular enhancement are expected.

Extramedullary hematopoiesis (EMH) is a physiological compensatory phenomenon in response to altered hematopoiesis occurring secondary to inadequate bone marrow function. EMH in the medical literature was commonly found in the liver and spleen whereas it is rarely seen in adrenal glands, breast, dura mater, and bowel. It often occurs in hemoglobinopathies, hemolytic anemias and myeloproliferative disorders.

Pathological causes of EMH in the adrenal gland were described in multiple case reports, which included the defects in hemoglobin production associated with sickle-cell disease, hemoglobin H constant spring disease, thalassemia and impaired red blood cell membrane production linked with hereditary spherocytosis.

The exact mechanism of EMH in the adrenal gland is unknown, but several hypotheses are suggested. The adrenal gland has hematopoietic capacity during the fetal period and EMH may develop from primitive rests in disease conditions. Other scientists believe that embolization of hematopoietic stem cells and homing in adrenal gland may occur. Chronic hypoxia is another presumptive cause of EMH.

Adrenal EMH might be clinically detected as incidentaloma, as happened in our case. Adrenal incidentaloma in association with hematologic disorders, e.g., agnogenic myeloid aplasia or beta thalassemia, needs careful imaging as well as adrenal hormonal investigations, in order to exclude malignancy and subclinical hypersecretory syndromes. Although EMH is a rare cause of an adrenal mass, the diagnosis must be considered in any patient with a history of a congenital haemolytic disorder, to avoid unnecessary surgical procedures.

CT adrenal of this patient showed a large heterogenous enhancing mass with necrotic area arising from the right adrenal gland. There are no specific diagnostic findings of extramedullary haematopoiesis in imaging studies. Adrenal EMH may appear as a homogeneous mass in ultrasonography (USG)/CT or as a heterogeneous mass with cystic change and calcification.

Although biopsy remains the gold standard for establishing a tissue diagnosis, it is an invasive procedure that carries the risk of catastrophic haemorrhage and is therefore not usually advocated. The Clinical Practice Guideline of the European Society of Endocrinology recommended against the use of an adrenal biopsy in the diagnostic work-up of patients with adrenal masses unless there is history of extra-adrenal malignancy. In this case, along with the paraspinal lesion, the leading diagnosis is extramedullary hematopoiesis. Hence, the patient’s clinical details and radiological pictures are extremely crucial in diagnosis.
In our case, EMH involved the right adrenal gland. It is interesting that our literature review on EMH also reported right-side predilection, where 13 out of 17 cases of EMH involved the right adrenal gland.6,11,13,17,25-30 Two cases involved the left adrenal gland, and two cases involved bilateral adrenal glands.16,31

A rather striking right-sided predominance was noted in a study done by Kenney et al., where 53 of 72 adrenal myelolipomas involved the right adrenal glands.36 Besides, in an analysis of adrenal myelolipomas conducted by Decmann et al., 260 tumors (59.2%) were on the right side, 111 on the left side (25.3%), while 54 tumors (12.3%) were bilateral.35

Although speculative, a possible explanation is that asymptomatic right-sided adrenal masses are more likely to be detected incidentally, particularly at ultrasound, owing to the fact that the right adrenal region is seen clearly during ultrasound examination of the gallbladder. It is not always possible to visualize the normal adrenal glands (especially on the left side) with an ultrasound.34,35

Treatment options for patients with EMH are described for thalassemia patients and depend on the location and symptoms. Different approaches included surgery, local radiation, blood transfusion and hydroxyurea.

There are published reports of incidentally detected adrenal masses in patients with haematological disorders, where adrenalectomy was performed, resulting in the histological surprise of EMH.5,11,12,17,25 Surgical excision is recommended in patients who are symptomatic and resistant to other modalities.15 However, the disadvantages of the surgical intervention include risk of excessive bleeding due to the high vascularity of the mass and high incidence of recurrence.36 In this case, patient is asymptomatic and hence, she was treated medically.

The medical approach involves hypertransfusion and oral hydroxyurea. Blood transfusion corrects the anaemia, and rapid neurologic improvement.40 However, Aliberti et al., reported two thalassaemic patients with spinal cord compression due to extramedullary haematopoiesis who achieved complete regression with blood hypertransfusion therapy.41 In the case presented above, the patient was given hypertransfusion and hydroxyurea. There was subsequent reduction in size of the right adrenal mass and paraspinal mass.

**CONCLUSION**

In conclusion, we presented a patient with thalassaemia intermedia who was referred due to an adrenal incidentaloma. With the background history of thalassaemia along with the presence of a paraspinous lesion, the leading diagnosis is extramedullary hematopoiesis. Although EMH is a rare cause of adrenal mass, the diagnosis must be considered in any patient with a history of a congenital hemolytic disorder, to avoid unnecessary surgical procedures.
