Abstract

Background: Infection with Salmonella enterica serovar Typhi (S. Typhi) with reduced susceptibility to fluoroquinolones has been associated with fluoroquinolone treatment failure. We studied the relationship between ofloxacin treatment response and the ofloxacin minimum inhibitory concentration (MIC) of the infecting isolate. Individual patient data from seven randomised controlled trials of antimicrobial treatment in enteric fever conducted in Vietnam in which ofloxacin was used in at least one of the treatment arms was studied. Data from 540 patients randomised to ofloxacin treatment was analysed to identify an MIC of the infecting organism associated with treatment failure.

Principal Findings: The proportion of patients failing ofloxacin treatment was significantly higher in patients infected with S. Typhi isolates with an MIC $\geq$0.25 μg/mL compared with those infections with an MIC of $\leq$0.125 μg/mL (p<0.001). Treatment success was 96% when the ofloxacin MIC was $\leq$0.125 μg/mL, 73% when the MIC was between 0.25 and 0.50 μg/mL and 53% when the MIC was 1.00 μg/mL. This was despite a longer duration of treatment at a higher dosage in patients infected with isolates with an MIC $\leq$0.25 μg/mL compared with those infections with an MIC of $\leq$0.125 μg/mL.

Significance: There is a clear relationship between ofloxacin susceptibility and clinical outcome in ofloxacin treated patients with enteric fever. An ofloxacin MIC of $\geq$0.25 μg/mL, or the presence of nalidixic acid resistance, can be used to define S. Typhi infections in which the response to ofloxacin may be impaired.

Introduction

Enteric fever is a systemic infection caused by Salmonella enterica serovar Typhi (S. Typhi) and Salmonella enterica serovar Paratyphi A (S. Paratyphi A) [1]. Antimicrobial therapy is critical for the clinical management of enteric fever. The emergence and sustained circulation of antimicrobial resistant organisms have become problematic in many endemic regions [1,2]. Multiple drug resistant S. Typhi (MDR: resistance to chloramphenicol, trimethoprim/sulfamethoxazole and ampicillin) have been widespread since the early 1990’s and hinder effective treatment and limit alternatives.

Fluoroquinolones are commonly used for treating enteric fever and have been recommended by the WHO for the treatment of uncomplicated enteric fever caused by fully sensitive and MDR organisms [3]. Ciprofloxacin and ofloxacin were chosen for treating typhoid because of potent bactericidal activity against S. Typhi and S. Paratyphi A, in vivo, both drugs have plasma levels considerably in excess of the prevailing MICs and excellent intracellular penetration [4]. Widespread use of fluoroquinolone therapy for enteric fever has been followed by the emergence of S. Typhi and S. Paratyphi A isolates with elevated minimum inhibitory concentrations (MIC) to ciprofloxacin and ofloxacin across Asia and in parts of Africa [5,6,7,8,9]. These strains are associated with point mutations in the gyrA gene and occasionally the parC gene [5,7,9,10,11,12]. To date, there have been few published reports of plasmid mediated quinolone resistance (PMQR) genes, such as qnr, aac(6’)-Ib-cr, or efflux pumps, in S. Typhi as described in some non-typhoidal Salmonella serovars [2,13]. The identification of strains with reduced susceptibility to fluoroquinolones is important to guide treatment, yet these strains are categorised as susceptible by the current guidelines for fluoroquinolone disk susceptibility testing [14,15,16]. Such isolates can be identified by using resistance to nalidixic acid as a surrogate marker of fluoroquinolone susceptibility, although this is not completely reliable [17,18]. Enteric fever caused by S. Typhi strains with an elevated MIC to ciprofloxacin and ofloxacin have been coupled with the failure of treatment with these antimicro-
Response to Ofloxacin in Typhoid Fever

Author Summary

Typhoid fever is an infection of the bloodstream caused by the organism Salmonella Typhi (S. Typhi). Treatment with antimicrobials is critical for preventing severe infection and even death, yet antimicrobial resistant organisms have become a problem in many places where typhoid is common. Fluoroquinolones are a group of antimicrobials that are commonly used to treat typhoid, we analysed data from 540 enteric fever patients treated with ofloxacin (a fluoroquinolone) to identify a level of resistance (minimum inhibitory concentration (MIC)) from the infecting organism which is associated with treatment failure. The proportion of patients failing treatment was higher in those infected with a bacterium with an MIC of 0.25 μg/mL, compared with those infections with an MIC of ≤0.125 μg/mL. Treatment success was 96% when the ofloxacin MIC was ≤0.125 μg/mL, yet only 53% when the MIC was 1.00 μg/mL. Our data demonstrates that an S. Typhi bacterium with an ofloxacin MIC of ≥0.25 μg/mL correlates with a poor outcome when treated with this antimicrobial. Therefore, we propose an amendment in the current MIC guidelines for microbiology laboratories to aid clinicians treating typhoid and suggest the use of alternative therapy in these patients.

Clinical procedures

Patients with suspected uncomplicated enteric fever were allocated to one of the treatment groups in an open randomised comparison. A computer generated randomisation list was produced by a member of staff that was not otherwise involved in the study. The treatment allocations were kept in serially numbered sealed opaque envelopes that were only opened after the patient had been enrolled into the study. The treatment arms were ofloxacin (Oflocet, Hoescht Marion Roussel, Paris, France) at a dose that varied between 10 and 20 mg/kg/day orally in two-divided dose (maximum 400 mg twice daily) for between two and seven days (depending on the study, or the comparator). The comparator arms were, either, a different regimen of ofloxacin (in three RCTs) [24,26,28] ceftriaxone [23], cefixime [29], or azithromycin (in two RCTs) [23,27].

Patients were excluded if they refused consent, had evidence of progressive or complicated disease, had inability to swallow oral medication, had a history of significant underlying disease, had hypersensitivity to either of the trial drugs or were pregnant or lactating. Additionally, patients who gave a history of treatment with a fluoroquinolone, a third generation cephalosporin or a macrolide within one week of hospital admission were also excluded.

Clinical definitions

In all seven studies, patients were examined daily until discharge from hospital, with particular reference to clinical symptoms and complications of the disease and body temperature was measured every six hours. Response to treatment was assessed by the resolution of clinical symptoms and signs, the fever clearance time (time from the start of treatment until the body temperature reached ≤38.0°C, and remained ≤38.0°C for 48 hours), the development of complications or death, any evidence of relapse of infection and persistent fecal carriage after the conclusion of treatment or at the one month follow up visit.

Clinical treatment failure was defined as the persistence of fever (≥38°C) and other enteric fever related symptoms for more than seven days after the initiation of treatment or the development of severe complications (severe gastrointestinal bleeding, intestinal perforation, visible jaundice, myocarditis, pneumonia, renal failure, shock or an altered conscious level) during treatment which required a change in therapy. Microbiological treatment failure was defined as isolation of S. Typhi from blood or a sterile site after the completion of treatment. Post study fecal carriage was defined as a positive fecal culture, with an isolate having the same susceptibility pattern as the original isolate, after the end of the initial treatment and before hospital discharge.

Patients were requested to return for a follow up assessment at four weeks or earlier if their symptoms recurred. Clinical evidence of relapse was sought and one fecal culture was performed. A blood culture was performed if the symptoms and signs suggested relapse. A relapse was defined as a recurrence of symptoms and signs suggestive of enteric fever within the four week period after the patient had been discharged well from the hospital accompanied by a blood culture positive for S. Typhi. One month faecal carriage was defined as a positive faecal culture at the one month follow up visit, with an isolate having the same susceptibility pattern as the original isolate.

Laboratory investigations and microbiology

A hematocrit, white cell, platelet count and blood differential count were performed with serum aspartate transaminase, alanine transaminase, creatinine levels and urinalysis before therapy was initiated. Aspartate transaminase and alanine transaminase measurements were repeated one day after the end of therapy.
A full blood count was repeated if there was a suggestion of gastrointestinal bleeding or clinical evidence of anaemia. Blood and fecal cultures were obtained before therapy and in one study a bone marrow was also performed in selected patients [27]. A blood culture was performed on all patients a day after the end of treatment. In addition, three fecal specimens were cultured between two and four days after the end of treatment and at the one month follow up visit. Bacterial culturing was performed as previously described [23,24,25,26,27,28,29], colonies presumptive of S. Typhi were identified using standard biochemical tests and serotype-specific antisera (Murex Biotech, Dartford, England).

Antimicrobial sensitivities were performed by the modified Bauer-Kirby disc diffusion method with zone size interpretation based on CLSI guidelines [30]. Antimicrobial discs tested were chloramphenicol (30 μg), ampicillin (10 μg), trimethoprim - sulphamethoxazole (1.25/23.75 μg), ceftriaxone (30 μg), ofloxacin (5 μg), azithromycin (15 μg) and nalidixic acid (30 μg). Isolates were stored in protect beads (Prolabs, Oxford, United Kingdom) at −20°C for later ofloxacin MIC testing by agar plate dilution [31]. Escherichia coli ATCC25922 and Staphylococcus aureus ATCC25923 were used as control strains for these assays. An isolate was defined as MDR if it was resistant to chloramphenicol (≥32 μg/ml), ampicillin (≥32 μg/ml) and trimethoprim/sulphamethoxazole (≥8/152 μg/ml). An isolate was defined as nalidixic acid resistant if it had an MIC of ≥32 μg/ml [15].

Statistical analysis

Analysis was restricted to patients in whom S. Typhi was isolated from blood or bone marrow culture prior to treatment with ofloxacin and in whom the ofloxacin MIC of the original infecting isolate had been determined. The pooled admission and outcome data for individual patients was compiled with respect to the ofloxacin MIC of the original infecting isolate. Proportions were compared with the Chi squared test, Fisher’s exact test or analysis of variance. Normally distributed data were compared using the Student t-test, non-normally distributed data using the Mann Whitney U test or Kruskall Wallis test. The fever clearance time was compared using survival analysis and the log rank test. Independent risk factors for clinical failure in the clinical trials were determined by multivariate logistic regression, a p value of <0.05 was considered significant. Statistical analysis was performed using SPSS for Windows version 10 (SPSS Inc, Chicago, USA).

Results

Clinical features of enteric fever patients treated with ofloxacin

A total of 540 patients infected with S. Typhi, treated with ofloxacin and in whom the ofloxacin MIC of the isolate was known from seven RCTs were available for analysis. The distribution of ofloxacin MIC values across the different trials is shown in Figure 1. The clinical features of the patients at the time of admission in relation to the ofloxacin MIC of the infecting S. Typhi isolate are shown in Table 1. There was heterogeneity among the six MIC (to ofloxacin) groups (≤0.06, 0.064, 0.125, 0.25, 0.50 and 1 μg/ml) with respect to a number of features, including the number of

patients in each group. Abdominal pain, vomiting and positive fecal cultures were more frequently observed in patients infected with an isolate with a higher ofloxacin MIC. Nalidixic acid resistance was observed in none of the 429 S. Typhi isolates with an ofloxacin MIC of \(<0.06 \mu g/mL\) in 2/12 (17\%) of isolates with an MIC of 0.125 \(\mu g/mL\) and 104/105 (99\%) of those with an MIC\(\geq 0.25 \mu g/mL\) \(p=0.001\) (Table 1).

### Clinical response of enteric fever patients to ofloxacin therapy

Details of the duration and dosage of ofloxacin treatment and the corresponding response to therapy are shown in Table 2. The median duration of therapy for patients infected with S. Typhi isolates with an MIC\(<0.125 \mu g/mL\) was three days at a median dose of 11 mg/kg. In patients infected with S. Typhi isolates with an MIC of between 0.125–0.25 \(\mu g/mL\) the median duration of therapy was three days at a median dose of 13–15 mg/kg. For patients infected with isolates with an MIC\(>0.25 \mu g/mL\) the median duration of therapy was seven days at a dose of 16–18 mg/kg.

We calculated the ratio of the administered dose of ofloxacin (mg/kg) to the MICs of the infecting isolates. The ratio of administered dose to bacterial MIC declined from 370 in patients infected with an S. Typhi isolate with an MIC of \(\leq 0.03 \mu g/mL\) to 18 in those infected with an S. Typhi isolate with an MIC of 1.0 \(\mu g/mL\). Despite a longer duration of treatment at a higher dosage, the proportion of patients failing treatment was significantly higher in the patients infected with S. Typhi isolates with an MIC\(\geq 0.25 \mu g/mL\) compared with those infected with isolates with an MIC of \(\leq 0.125 \mu g/mL\) \(p=0.001\). Concurrently, the time to fever clearance was significantly longer in the patients with a higher MIC (Figure 2 and Table 2). There was an evident relationship between fever clearance time and the MIC of the infecting organism, as shown in Figure 3. Furthermore, the proportion of patients with a positive faecal culture, immediately post study treatment and at one month follow-up was also significantly greater among the patients infected with an isolate with a higher MIC to ofloxacin, \(p<0.001\) and \(p=0.001\) respectively (Table 2).

### Predicting clinical failure to ofloxacin therapy in enteric fever patients

Univariate analysis was performed to identify the factors that were associated with clinical failure. The presence of abdominal pain \(p<0.001\), diarrhoea \(p=0.03\), vomiting \(p<0.001\), lower hemocrit \(p=0.03\), lower white cell count \(p=0.04\), lower platelet count \(p=0.002\), infection with an S. Typhi organism with a higher ofloxacin MIC \(p<0.001\), prolonged duration of ofloxacin treatment \(p<0.001\) and a higher administered dose of ofloxacin \(p=0.009\) were all associated with clinical failure. Duration of therapy was deliberately increased as the MIC increased. If this factor is not included in the model, the independent variables associated with clinical failure with ofloxacin treatment using a multivariate logistic regression model were, abdominal pain, Odds Ratio (OR) 0.461, 95\% confidence Interval (95\% CI) 0.233–0.969, \(p=0.033\), vomiting; OR 0.427, 95\% CI; 0.208–0.876, \(p=0.020\), hemocrit; OR 0.924, 95\% CI; 0.861–0.992, \(p=0.033\), platelet count; OR 0.990, 95\% CI; 0.984–1.00, \(p=0.001\) and the ofloxacin MIC of the infecting isolate; OR 17.08, 95\% CI; 6.62–44.04, \(p<0.001\).

To define an appropriate ofloxacin MIC breakpoint and the use of nalidixic acid resistance to define clinical failure to ofloxacin, the clinical success rate in each MIC group was calculated (Table 3). The data stratified by MIC to ofloxacin suggests a treatment

Figure 2. The relationship between increasing S. Typhi MIC to ofloxacin and clinical failure. Histogram showing the proportion of enteric fever patients who failed treatment (white columns) or had persistent fever (black columns) (>38°C) for more than seven days after the commencement of treatment. Data was combined from seven randomised clinical trials and is comprised from 540 children and adults recruited with uncomplicated enteric fever. The patients are divided according to the MIC to ofloxacin of the infecting isolate.

doi:10.1371/journal.pntd.0001163.g002
success rate with ofloxacin given for a median duration of 3 days at 11–13 mg/kg of 96% in 435 patients infected with an isolate with an ofloxacin MIC of $0.125 \text{ mg/mL}$; 73% in 67 patients infected with isolate with an ofloxacin MIC between 0.25 and 0.5 mg/mL with treatment durations between 3 to 7 days at 15–16 mg/kg; and 53% in 38 patients infected with an isolate with an ofloxacin MIC of 1.00 mg/mL despite a median duration of treatment of 7 days at 18 mg/kg. The success rate in 434 patients infected with a nalidixic acid susceptible isolate was 96% compared with a 65% success rate in the 106 patients infected with a nalidixic acid resistant isolate.

**Discussion**

In this study we used individual patient data from seven randomised controlled trials to characterise the relationship between ofloxacin susceptibility and outcome in ofloxacin treated patients with uncomplicated enteric fever. There was clear relationship between a higher ofloxacin MIC of the infecting isolate and a declining response to ofloxacin. Although the trials were conducted according to a standard protocol, the duration and dosage of ofloxacin treatment was not standard across all patient groups and the duration for some patients was shorter than would be routinely recommended. Despite this, a successful response in 96% of patients to an average duration of treatment of three days among infections with an ofloxacin MIC $\leq 0.25 \text{ mg/mL}$ indicates the efficacy of ofloxacin when isolates are fully susceptible and justifies comparison with the response to infections where the isolate had a higher MIC and the ofloxacin dose used was higher and duration longer.

Our data suggests an MIC breakpoint for ofloxacin of $\geq 0.25 \text{ mg/mL}$ or the presence of nalidixic acid resistance could be used to define infections in which the response to ofloxacin is impaired. The ciprofloxacin MIC is usually one dilution less than ofloxacin, and this implies a ciprofloxacin breakpoint of $\geq 0.125 \text{ mg/mL}$, a breakpoint already suggested [32,33]. The small number of infections with isolates with an MIC of 0.125 mg/mL is a limitation and more information on the response to treatment at this MIC would be valuable. As nalidixic acid resistance is not a reliable proxy marker for reduced fluoroquin-
olone susceptibility in S. Typhi [17] we endorse the re-evaluation of disk susceptibility breakpoints for fluoroquinolones against S. Typhi by the clinical and laboratory standards institute (CSLI) [34]. This study only includes infections with S. Typhi so we can only propose applying similar breakpoints for S. Paratyphi A. Antimicrobial resistant S. Paratyphi A is an emerging problem in Asia and similar clinical characterisation of S. Paratyphi A infections is required [35].

A number of previous studies have reported an impaired response in typhoid fever to ciprofloxacin or ofloxacin when the isolates have decreased susceptibility. In general these studies are case reports or case series, mostly retrospective, or small numbers of patients in clinical trials. Despite these reports there has been a reluctance to change the MIC and disc susceptibility breakpoints for ciprofloxacin and ofloxacin and Salmonella. The data presented in this study were collected prospectively in the context of randomised controlled trials with uniform methods of collecting the treatment outcomes, during a period when the proportion of S. Typhi strains with reduced susceptibility to ciprofloxacin and ofloxacin changed from negligible to the majority. Reduced susceptibility to fluoroquinolones in the strains isolated during the period when these studies were conducted were predominantly associated with point mutations in gyrA and were typical of strains from other locations at this time [3]. This is a unique set of data that is unlikely to be repeated, with sufficient numbers of cases to provide a clear and definitive demonstration that an elevated MIC to ofloxacin is associated with treatment failure. We feel that the data are sufficiently convincing that it should now lead to a change in the MIC and disc susceptibility breakpoints for S. Typhi with ofloxacin and, potentially, ciprofloxacin.

Pharmacokinetic and pharmacodynamic (PK-PD) parameters are likely to be an important factor in the response to fluoroquinolone therapy. A study using an in vitro model of S. Typhi infection and Monte Carlo simulations to explore PK-PD parameters that were predictive of efficacy found that the free drug area under the concentration-time curve from 0 to 24 h/MIC ratio (AUC/MIC ratio) was the parameter most predictive of efficacy and that a ratio of 105 corresponded to 90% of maximal activity [36]. The pharmacokinetics of ofloxacin was not measured in the trials studied here. However, using the dose/kg of ofloxacin given as a crude measure of drug exposure, the data in this analysis suggests that when the ratio of the mean ofloxacin dose/kg divided by the MIC of the infecting organism is above 100 the treatment response is satisfactory, but when it is below 100 the treatment response is impaired. It should be noted that the plasma concentration of fluoroquinolone in individual patients given the same dose is variable. This, as well as other factors such as age and immune status, may explain why not all patients that have an organism with an MIC $\geq$ 0.25 $\mu$g/mL will fail therapy. We suggest that future trials in enteric fever should include pharmacokinetic measurements to allow proper analysis of PK-PD parameters.

Some studies have suggested a higher rate of life-threatening complications in patients infected with S. Typhi isolates with decreased susceptibility to fluoroquinolones [22]. In this study there were no significant differences in the rate of life-threatening complications between the patients infected with isolates with different MICs. The rate of patients with life-threatening complications (2.2%) was lower than would be the case in unselected patients, as the subjects selected for these trials were specifically screened for uncomplicated disease at enrolment.

Conclusions

S. Typhi strains that exhibit MICs to ofloxacin that are higher than those observed in this study are emerging and the ongoing use of fluoroquinolones, such as, ofloxacin and ciprofloxacin, to treat S. Typhi infections with reduced susceptibility may be driving their selection [13,37,30]. The increased fecal carriage following ofloxacin treatment of isolates with reduced ofloxacin susceptibility is also likely to drive increased local transmission. We suggest azithromycin, a third generation cephapolorin, or a later generation fluoroquinolone to be considered as alternatives for MDR S. Typhi isolates with an ofloxacin MIC of $\geq$0.25 $\mu$g/mL [20,27,39,40]. Yet, there is an obvious risk of emerging resistance to these alternative antimicrobial agents [41] and dosing regimens need careful design to prevent this. Our data demonstrates that an S. Typhi isolate with an ofloxacin MIC of $\geq$0.25 $\mu$g/mL correlates with a poor clinical outcome when treated with this antimicrobial and we propose an amendment in the S. Typhi susceptibility breakpoints for ofloxacin and ciprofloxacin [34].

Acknowledgments

We thank the Directors and the clinical and microbiology staff of the Hospital for Tropical Diseases, Ho Chi Minh City; Dr Vo Anh Ho and colleagues at Dong Thap Provincial Hospital, Dong Thap Province; and the late Dr Cao Xuan Thanh Phuong and colleagues at Dong Nai Paediatric Centre, Dong Nai Province, Vietnam for their support of these studies.
