ABSTRACT

We discuss new Keck/MOSFIRE spectroscopic observations of four luminous galaxies at $z \approx 7 - 9$ selected to have intense rest-frame optical line emission by Roberts-Borsani et al. (2016). Previous spectroscopic follow-up has revealed Ly$\alpha$ emission in two of the four galaxies. Our new MOSFIRE observations confirm that Ly$\alpha$ is present in the entire sample. We detect Ly$\alpha$ emission in the galaxy COS-zs7-1, confirming its redshift as $z_{\text{Ly}\alpha} = 7.154$, and we detect Ly$\alpha$ in EGS-zs8-2 at $z_{\text{Ly}\alpha} = 7.477$, verifying a tentative detection presented in an earlier study. The ubiquity of Ly$\alpha$ emission in this unique photometric sample is puzzling given that the IGM is expected to be significantly neutral over $7 < z < 9$. To investigate this surprising result in more detail, we have initiated a campaign to target UV metal line emission in the four Ly$\alpha$ emitters as a probe of both the ionizing radiation field and the velocity offset of Ly$\alpha$ at early times. Here we present the detection of very large equivalent width [CIII], $\lambda\lambda 1907, 1909$ Å emission in EGS-zs8-1 ($W_{\text{CIII}} = 22 \pm 2$ Å), a galaxy from this sample previously shown to have Ly$\alpha$ emission at $z = 7.73$. Photoionization models indicate that an intense radiation field ($\log_{10} \xi_{\text{ion}} [\text{erg}^{-1} \text{Hz}] \approx 25.6$) and moderately low metallicity ($0.11 Z_{\odot}$) are required to reproduce the CIII] line emission and intense optical line emission implied by the broadband SED. We argue that this extreme radiation field is likely to affect the local environment, increasing the transmission of Ly$\alpha$ through the galaxy. Moreover, the centroid of CIII] emission indicates that Ly$\alpha$ is redshifted from the systemic value by 340 km sec$^{-1}$. This velocity offset is larger than that seen in less luminous systems and provides an additional explanation for the transmission of Ly$\alpha$ emission through the intergalactic medium. Since the transmission is further enhanced by the likelihood that such systems are also situated in the densest regions with accelerated evolution and the largest ionized bubbles, the visibility of Ly$\alpha$ at $z > 7$ is expected to be strongly luminosity-dependent, with the most effective transmission occurring in systems with intense star formation.

1 INTRODUCTION

The reionization of intergalactic hydrogen is an important milestone in early cosmic history, marking the point at which nearly ev-
ery baryon in the universe was affected by the growth of structure. How and when reionization occurs encodes unique insight into the nature of the first luminous objects, motivating a number of dedicated observational efforts aimed at studying the process. Significant progress has been made in the last decade. Measurement of the optical depth to electron scattering faced by the CMB reveals that the process is underway by $z \approx 6$ (Planck Collaboration et al. 2015, 2016), while quasar absorption spectra indicate that reionization is largely complete by $z \approx 6$ (e.g., Fan et al. 2006; McGreer et al. 2015). The large abundance of faint $z \geq 6$ galaxies identified photometrically with the WFC3/IR camera on the Hubble Space Telescope (e.g., McLure et al. 2013; Bouwens et al. 2015b; Finkelstein et al. 2015) suggests that the ionizing output of star forming systems may be sufficient to complete reionization by $z \approx 6$ while also supplying the measured Thomson scattering optical depth of the CMB (Robertson et al. 2015; Bouwens et al. 2015a; Stanway et al. 2016).

New insight is now being provided by spectroscopic surveys targeting Ly$\alpha$ emission from star forming galaxies at $z \geq 6$. Since Ly$\alpha$ is resonantly scattered by neutral hydrogen, the fraction of galaxies that exhibit prominent Ly$\alpha$ emission should fall abruptly during the reionization era (Fontana et al. 2010; Stark et al. 2010). Throughout the past five years, a large investment has been devoted to searches for Ly$\alpha$ emission in the reionization era, resulting in only nine robust detections of Ly$\alpha$ at $z > 7$ (Vanzella et al. 2011; Ono et al. 2012; Schenker et al. 2012; Shibuya et al. 2012; Finkelstein et al. 2013; Oesch et al. 2013; Zitrin et al. 2015; Song et al. 2016). These surveys clearly reveal a rapidly declining Ly$\alpha$ emitter fraction over $6 < z < 8$ (e.g., Stark et al. 2010; Fontana et al. 2010; Ono et al. 2012; Penttucci et al. 2013; Hathi et al. 2014; Schenker et al. 2014), similar to the drop in the abundance of narrowband-selected Ly$\alpha$ emitters over $5.7 < z < 7.3$ (e.g., Konno et al. 2014). The decline in the volume density of Ly$\alpha$ emitters at $z > 6.5$ is consistent with strong attenuation from intergalactic hydrogen, possibly requiring neutral fractions of $x_HI \geq 0.3 - 0.5$ at $z \approx 7 - 8$ (Mesinger et al. 2015; Choudhury et al. 2015). In this framework, the small sample of known $z > 7$ systems with detectable Ly$\alpha$ emission is thought to be galaxies that are situated in the largest ionized regions of the IGM, allowing Ly$\alpha$ to redshift well into the damping wing before encountering intergalactic hydrogen.

The first clues that this physical picture may be incomplete have recently begun to emerge. The detection of nebular CIV emission in a low luminosity $z = 7.045$ Ly$\alpha$ emitter (A1703-zd6) led Stark et al. (2015b) to speculate that this galaxy’s hard ionizing spectrum may enhance its Ly$\alpha$ transmission by efficiently ionizing surrounding hydrogen. If true, this would suggest that observed counts of $z > 7$ Ly$\alpha$ emitters may also depend on the prevalence of galaxies with extreme radiation fields, adding uncertainty to the modeling of the evolving Ly$\alpha$ transmission at $z > 6$. Observational efforts are now underway to establish how common such hard ionizing spectra are among reionization-era galaxies and to constrain the powering mechanism (AGN or metal poor stars) of the nebular CIV emission (e.g., Feltre et al. 2016).

Perhaps even more puzzling is the discovery of Ly$\alpha$ in the first two galaxies observed from a recent selection of the most luminous $z > 7$ galaxies in the CANDELS fields (Roberts-Borsani et al. 2016), including record-breaking detections at $z = 7.73$ (Oesch et al. 2015) and $z = 8.68$ (Zitrin et al. 2015). The Roberts-Borsani et al. (2016) hereafter RB16) photometric sample includes a total of four galaxies, each very bright in WFC3/IR imaging ($H_{160} = 25.0 - 25.3$) with very red Spitzer/IRAC [3.6]-[4.5] colors, indicating extremely large equivalent width [OIII]+H$\beta$ emission. How Ly$\alpha$ emission is able to escape efficiently from these systems while being so strongly attenuated from most other early galaxies is unclear. One possibility is that the most luminous galaxies trace overdense regions which produce the largest ionized bubbles at any given redshift (e.g., Barkana & Loeb 2004; Furlanetto et al. 2003, 2004; Zitrin et al. 2015) speculated that the selection of galaxies with red IRAC colors may pick out systems with hard ionizing spectra which are able to create early ionized bubbles, enhancing the transmission of Ly$\alpha$ through the IGM.

With the aim of improving our understanding of the factors which are most important in regulating the escape of Ly$\alpha$ at $z > 7$, we have recently initiated a comprehensive spectroscopic survey of Ly$\alpha$ and UV metal emission lines in the full photometric sample of galaxies identified in Roberts-Borsani et al. (2016). Our goals are twofold. Firstly, we seek a complete census of the Ly$\alpha$ emission equivalent widths. Thus far, only two of the four RB16 galaxies have been spectroscopically confirmed. A third system (EGS-zs8-2) was found to have a tentative Ly$\alpha$ emission feature at $z = 7.47$ in Roberts-Borsani et al. (2016), and the fourth system (COSY-0237620370, hereafter COS-zs7-1) has yet to be observed. Second, we aim to use knowledge of the UV metal emission line properties to understand the evolving popularity of Ly$\alpha$ emission at $z > 7$. In particular, we wish to characterize the hardness of the ionizing spectrum, determining if the RB16 galaxies are similar to the nebular CIV emitting $z = 7.045$ galaxy reported in Stark et al. (2015b). Using the systemic redshift provided by the [CII], [CII]λ1589,1909 doublet, we will investigate the velocity offset of Ly$\alpha$ in the RB16 sample, one of the most important parameters governing the IGM attenuation provided to Ly$\alpha$ in the reionization era.

We adopt a Λ-dominated, flat Universe with $\Omega_{\Lambda} = 0.7$, $\Omega_M = 0.3$ and $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$. All magnitudes in this paper are quoted in the AB system (Oke & Gunn 1983).

### 2 KECK/MOSFIRE OBSERVATIONS AND ANALYSIS

We present new observations of three of the four galaxies identified in Roberts-Borsani et al. (2016). Data were obtained over three separate observing runs using the near-infrared multi-object spectrograph MOSFIRE (McLean et al. 2012) on the Keck I telescope. Details of the MOSFIRE observations are summarized in Table 1. The first observing run was 12-15 April 2015. We observed EGS-zs8-2 in the Y-band, targeting the tentative Ly$\alpha$ detection reported in Roberts-Borsani et al. (2016). The seeing was between 0.7 and 0.8 and skies were clear for 4.0 hours of integration. The integration time of individual Y-band exposures was 180 seconds. Both EGS-zs8-1 and EGS-zs8-2 were then observed in the H-band to constrain the strength of the [CII],[CII]λ1589,1909 doublet. Conditions were mostly clear and seeing was 0.6 during the 2.5 hours of on-source integration. On 11 June 2015, we obtained an additional 1.0 hr of H-band observations on EGS-zs8-1 and EGS-zs8-2 in clear conditions with average seeing of 0.6, bringing the total H-band integration time to 3.5 hrs. The individual H-band exposures are 120 seconds. Finally, on 30 November 2015, we obtained a Y-band spectrum of COS-zs7-1. Conditions were clear and the average seeing was 0.7. We obtained 48 exposures of 180 seconds, totaling 2.4 hours of on-source Y-band integration on COS-zs7-1. Each mask contained 1-2 isolated stars for absolute flux calibration and numerous lower redshift galaxies. We used slit widths of 0.7 on all three observing runs.
The publicly-available MOSFIRE Data Reduction Pipeline (DRP) was used to reduce the spectra. The DRP performs flat-fielding, wavelength calibration, sky-subtraction, and cosmic ray removal, outputting reduced two dimensional spectra. For our chosen slit width, MOSFIRE provides a resolving power of $R \approx 3388$ (Y-band) and $R \approx 3600$ (H-band), delivering a resolution of 2.82 Å and 2.74 Å in Y and H-band, respectively, for slit widths of 0.7′. Using the output from the DRP, we calculated two-dimensional signal to noise maps for each object. One-dimensional spectra were then obtained using a boxcar extraction with apertures matched to the object profile, typically in the range 6-8 pixels (1″-8″). The flux calibration was performed in two stages. We determined the telluric correction spectrum via longslit observations of a spectrophotometric standard star conducted prior to the observations. The resulting correction spectrum accounts for the effects of the atmosphere and the instrumental response. The absolute flux scale is calculated using the spectra of stars that were placed on the mask. Using the HST flux measurements of the stars, we calculate the average scaling factor necessary to convert the observed count rate into flux density. The absolute scaling factor is applied to the telluric correction spectrum, resulting in a wavelength-dependent flux calibration which we apply to the 1D-extracted spectra. If the sources are more extended than the stars used for the flux calibration, a small aperture correction will be required to account for slit losses. We calculate the aperture correction individually for each source by convolving the HST images with the ground-based seeing. Given the very small sizes of the $z > 7$ galaxies, these corrections are found to be negligible for the sources considered in this paper.

3 RESULTS

3.1 EGS-zs8-1

EGS-zs8-1 is a bright (H$_{160}$=25.0) galaxy with a red IRAC color ([3.6]-[4.5]=0.53 ± 0.09). As described in Roberts-Borsani et al. (2016), the 4.5μm flux excess suggests very large rest-frame equivalent width (911 ± 122Å) [OII]+Hβ emission. The optical line equivalent widths quoted here and below are inferred through computation of the line flux required to produce the measured IRAC flux excess, in the same manner as earlier studies (Shim et al. 2011; Stark et al. 2013; Smit et al. 2013; 2015a; Roberts-Borsani et al. 2016). The spectroscopic redshift was confirmed by Oesch et al. (2013) through detection of a strong Lyα emission line using MOSFIRE (see Figure 3a). The line reaches peak flux at 10616 Å corresponding to $z_{\text{Ly}\alpha} = 7.73$. Oesch et al. (2015) fit a truncated Gaussian profile to the data and calculate a redshift of $z_{\text{Ly}\alpha} = 7.73$. Since the true line profile is very uncertain, we will adopt the redshift set by the peak line flux for our analysis. As we detail below, the result does not strongly impact our conclusions. The Lyα line flux ($1.7 \times 10^{-17}$ erg cm$^{-2}$ s$^{-1}$) is one of the largest among $z > 7$ galaxies and suggests a rest-frame equivalent width of W$_{\text{Ly}\alpha} = 21 ± 4$ Å. The absolute magnitude ($M_{\text{UV}} = -22.1$) indicates an unusually luminous galaxy, roughly 3× brighter than the value of $L_{\text{UV}}$ derived from the Schechter parameter fitting functions presented in Bouwens et al. (2015b).

The MOSFIRE H-band spectrum of EGS-zs8-1 covers the wavelength range between 1.5154 μm and 1.8223 μm. In Figure 4, the narrow spectral window between 1.650 and 1.675μm is shown, revealing a clean detection of both components of the [CII], [CIII] doublet. We measure line fluxes of $4.5 \pm 0.5 \times 10^{-18}$ erg cm$^{-2}$ s$^{-1}$ and $3.6 \pm 0.5 \times 10^{-18}$ erg cm$^{-2}$ s$^{-1}$ for the 1907 and 1909 Å components, respectively. The total flux in the resolved [CII] doublet is close to 50% that of Lyα, nearly 10× greater than is seen in the most extreme [CII] emitting galaxies at lower redshift (e.g., Erb et al. 2010; Stark et al. 2014). Since the continuum is undetected in the spectrum, we calculate the rest-frame equivalent widths using continuum flux derived from the broadband SED. The measurements indicate a total [CII], [CIII] rest-frame equivalent width of 22 ± 2 Å (12 ± 2 Å for [CII]1907 and 10 ± 1 Å for [CII]1909), similar to the value recently derived in a gravitationally-lensed galaxy at $z = 6.024$ (Stark et al. 2015a).

The flux ratio of the [CII], [CIII] doublet provides a measurement of the electron density of the ionized gas. The ratio of [CII]1907/[CII]1909 varies from $\sim 0.8$ for $n_e = 3 \times 10^4$ cm$^{-3}$ to 1.5 for $n_e = 10^5$ cm$^{-3}$. The measured [CII]1907/[CII]1909 flux ratio of EGS-zs8-1 (1.25 ± 0.22) suggests that CIII1 traces reasonably high density gas. The electron density of the system is determined by using IRAF’s NEBULAR package (Shaw & Dufour 1995). Assuming an electron temperature of 15,000 K, consistent with metal poor CIII1 emitting galaxies at lower redshifts (e.g., Erb et al. 2010; Stark et al. 2015a and well in excess of Choudhury et al. 2015). Yet owing to the lack of strong nebular emitters to IGM ionization state (e.g., Erb et al. 2010; Christensen et al. 2012; Stark et al. 2014), providing a valuable measure of the IGM ionization state (e.g., Choudhury et al. 2015).

The detection of CIII1 also constrains the systemic redshift (e.g., Stark et al. 2014), providing a valuable measurement of the velocity offset of Lyα, $\Delta v_{\text{Ly}\alpha}$. The Lyα velocity offset is a key input parameter for models which seek to map the evolving number counts of Lyα emitters to IGM ionization state (e.g., Choudhury et al. 2015). Yet owing to the lack of strong nebular lines in reionization-era galaxies, there are currently only a handful of $\Delta v_{\text{Ly}\alpha}$ measurements at $z > 6$ (Willott et al. 2015; Stark et al. 2015a). The wavelength centroids of the [CII], [CIII] doublet in EGS-zs8-1 reveal a systemic redshift of 7.723. The peak of the emergent Lyα emission line occurs at 10616 Å, implying a velocity offset of $\Delta v_{\text{Ly}\alpha} = 340_{-30}^{+35}$ km s$^{-1}$. The FWHM of the Lyα line (360 km s$^{-1}$; Oesch et al. 2015) thus indicates that a substantial fraction of the Lyα flux leaves the galaxy between 340 km s$^{-1}$ and 520 km s$^{-1}$. We note that if we were to adopt the truncated gaussian redshift for Lyα, the inferred velocity offset would be somewhat smaller (260 km s$^{-1}$), but more importantly, the line profile still would imply a significant amount of flux emerging at yet larger velocities. The mean velocity offset of EGS-zs8-1 is comparable to the two measurements presented in Willott et al. 2015, but is considerably larger than that inferred in a robustly-detected CIII1 emitter at $z = 6.024$ (Stark et al. 2015a) and well in excess of the $\Delta v_{\text{Ly}\alpha}$ parameterization adopted in the reionization models of Choudhury et al. 2015. We discuss the implications of these findings for reionization in §5.2.
EGS-zs8-2 is another bright (H<sub>160</sub>=25.1) galaxy identified in CANDELS imaging by RB16. The IRAC color of EGS-zs8-2 ([3.6]-[4.5]=0.96 ± 0.17) is redder than EGS-zs8-1, likely reflecting yet more extreme optical line emission. We estimate a rest-frame [OIII]+Hβ equivalent width of 1610 ± 302 Å is required to reproduce the flux excess in the [4.5] filter. A 4.7σ emission feature was identified by Roberts-Borsani et al. (2016) at a wavelength of 1.031μm. RB16 tentatively interpret this feature as Lyα.

We obtained a Y-band spectrum of EGS-zs8-2 with the goal of verifying the putative Lyα detection. The spectrum we obtained shows a 7.4σ emission line at 1.0305 μm (Figure 2b), confirming that EGS-zs8-2 is indeed a Lyα emitter at z<sub>Lyα</sub> = 7.477. The measured line flux (7.4 ± 1.0 × 10^-18 erg cm^-2 s^-1) is less than half that of EGS-zs8-1. We calculate the Lyα equivalent width using the broadband SED to estimate the underlying continuum flux. The resulting value (W<sub>Lyα</sub>=9.3 ± 1.4 Å) is the smallest of the RB16 galaxies.

The MOSFIRE H-band spectrum covers 14587 to 17914 Å, corresponding to rest-frame wavelengths between 1720 and 2113 Å for EGS-zs8-2. In Figure 2b, we show the spectral window centered on the [CIII], CIII] doublet. No emission lines are visible. There are two weak sky lines in the wavelength range over which the doublet is situated. However the separation of the individual components of the doublet is such that at least one of the two lines must be located in a clean region of the spectrum. We estimate 3σ upper limits of 2.3×10^-18 erg cm^-2 s^-1 for individual components. The non-detection suggests that the total flux in the CIII] doublet must be less than 62% of the observed Lyα flux, fully consistent with the ratio observed in EGS-zs8-1 and in extreme CIII] emitters at lower redshift. We place a 3σ upper limit on the doublet rest-frame equivalent width of <14 Å. Deeper data may yet detect CIII] in EGS-zs8-2.

Table 1. Galaxies targeted with Keck/MOSFIRE spectroscopic observations. The final column provides the reference to the article where each galaxy was first discussed in the literature. The photometric redshifts shown in column three are taken from the discovery papers. References: [1] Roberts-Borsani et al. (2016); [2] Oesch et al. (2015).

The top panels show the two dimensional SNR maps (black is positive), and the bottom panel shows the flux calibrated one-dimensional extractions.

3.2 EGS-zs8-2

Prior to this paper, COS-zs7-1 was the only source from Roberts-Borsani et al. (2016) lacking a near-infrared spectrum. Similar to the other galaxies from RB16, COS-zs7-1 is bright in the near-infrared (H<sub>160</sub>=25.1) and has IRAC color ([3.6]-[4.5]=1.03 ± 0.15) that indicates intense optical line emission. In addition to RB16, the galaxy has been reported elsewhere (e.g., Tilvi et al. 2013; Bowler et al. 2014). We estimate an [OIII]+Hβ rest-frame equivalent width of 1854 ± 325 Å based on the [4.5] flux excess, making COS-zs7-1 the most extreme optical line emitter in the RB16 sample. RB16 derive a reasonably well-constrained photometric redshift
et al. (2012); [10] Stark et al. (2015b); [11] Vanzella et al. (2011).

Table 2. Rest-UV emission line properties of \( z > 7 \) spectroscopically confirmed galaxies. The top half of the table shows the targets observed in this paper. In the bottom half of the table, we include measurements for other sources in the literature with spectroscopic redshifts above \( z = 7 \). The equivalent widths include the aperture correction and are quoted in the rest-frame. The upper limits are \( 3\sigma \). References: [1] Oesch et al. (2015); [2] Roberts-Borsani et al. (2016); [3] Zitrin et al. (2015); [4] Song et al. (2016); [5] Finkelstein et al. (2013); [6] Tilvi et al. (2016); [7] Shibuya et al. (2012); [8] Ono et al. (2012); [9] Schenker et al. (2012); [10] Stark et al. (2015b); [11] Vanzella et al. (2011).

\( z_{\text{phot}} = 7.477 \) that places \( \text{Ly}\alpha \) in a narrow 290 Å window between 9750 and 10041 Å.

The Keck/MOSFIRE Y-band spectrum spans between 9750 Å and 11238 Å, covering the full range over which \( \text{Ly}\alpha \) is predicted to lie. We identify a 6.25σ emission line at 9913 Å that is coincident with the expected spatial position of \( \text{COS}-z\text{s7-1} \) (Figure 3). The emission line is seen to have the standard negative - positive - negative pattern, indicating that it is present in both dither positions. If the feature is \( \text{Ly}\alpha \), it would correspond to \( z_{\text{Ly}\alpha} = 7.154 \), in excellent agreement with the photometric redshift derived by RB16. No other emission lines are visible at the spatial position of \( \text{COS}-z\text{s7-1} \) in the Y-band spectrum. We conclude that \( \text{Ly}\alpha \) is the most likely interpretation of the line given the pronounced dropout in the \( z \)-band and the evidence for strong \([\text{OIII}]+\text{H}\beta \) emission in the [4.5] filter. The emission line is clearly distinct from sky lines with emission spanning 9905-9915 Å; however the red side of the line coincides with positive residuals from a weak OH line at 9917 Å, complicating the line flux measurement. Integrating the emission line blue-
ward of the OH line, we find a total flux of $2.5 \pm 0.4 \times 10^{-17}$ erg cm$^{-2}$ s$^{-1}$ and a rest-frame Ly$\alpha$ equivalent width of $28 \pm 4$ Å.

Table 2 summarizes the various emission line measures and the related physical properties for all three sources in the context of earlier work.

### 4 PHOTOIONIZATION MODELING

The broadband SEDs of the RB16 galaxies suggest the presence of extremely large equivalent width [OIII]+H$\beta$ emission. Here we investigate whether the available data require an intense radiation field that may favor the escape of Ly$\alpha$. In the case of EGS-zs8-1 and EGS-zs8-2, we fold in the new constraints on [CII], [CIII] emission. We focus our analysis on the three galaxies from RB16 for which we have obtained new spectral constraints (COS-zs7-1, EGS-zs8-1, EGS-zs8-2). We fit the available emission-line and broadband fluxes using the Bayesian spectral interpretation tool BEAGLE (Chevallard & Charlot 2016), which incorporates in a flexible and consistent way the production of radiation in galaxies and its transfer through the interstellar and intergalactic media.

The version of BEAGLE used here relies on the models of Gutkin et al. (in preparation), who follow the prescription of Charlot & Longhetti 2001 to describe the emission from stars and the interstellar gas, based on a combination of the latest version of the Bruzual & Charlot 2003 stellar population synthesis model with the standard photoionization code CLOUDY (Ferland et al. 2013).

The main adjustable parameters of the photoionized gas are the interstellar metallicity, $Z_{\text{ism}}$, the typical ionization parameter of newly ionized H$\Pi$ regions, $U_S$ (which characterizes the ratio of ionizing-photon to gas densities at the edge of the Stroömgren sphere), and the dust-to-metal mass ratio, $\xi_d$ (which characterizes the depletion of metals on to dust grains). We consider here models with hydrogen density $n_H = 100$ cm$^{-3}$, and two values of C/O abundance ratios, equal to 1.0 and 0.5 times the standard value in nearby galaxies [(C/O)$_{0}$ = 0.44]. Attenuation by dust is described using the 2-component model of Charlot & Fall (2000), combined with the Chevallard et al. (2013) ‘quasi-universal’ prescription to account for the effects linked to dust/star geometry (including ISM clumpiness) and galaxy inclination. Finally, we adopt the prescription of Inoue et al. (2014) to include absorption by the IGM.

We parametrize the star formation histories of model galaxies in BEAGLE as exponentially delayed functions $\psi(t) \propto t e^{-t/\tau_{\text{SFR}}}$, for star formation timescale in the range $7 \leq \tau_{\text{SFR}}$ (yr) $\leq 10.5$ and formation redshift in the range $z_{\text{obs}} \leq z_{\text{form}} \leq 50$ (where $z_{\text{obs}}$ is the observed galaxy redshift). We adopt a standard Chabrier (2003) initial mass function and assume that all stars in a given galaxy have the same metallicity, in the range $-2.2 \leq \log(Z/Z_\odot) \leq -0.25$. We superpose on this smooth exponential function a current burst with a fixed duration 10 Myr, whose strength is parametrized in terms of the specific star formation rate, in the range $-14 \leq \log(\psi/\text{yr}^{-1}) \leq -7$. We adopt the same interstellar and stellar metallicity ($Z_{\text{ism}} = Z$) and let the dust-to-metal mass ratio and ionization parameter freely vary in the range $\xi_d = 0.1 - 0.5$ and $4 \leq \log(U_S) \leq 1$, respectively. We consider V-band dust attenuation optical depths in the range $-3 \leq \log(\tau_V) \leq 0.7$ and fix the fraction of this arising from dust in the diffuse ISM rather than in giant molecular clouds to $\mu = 0.4$ (Wild et al. 2011).

With this parametrization, we use BEAGLE to fit the available constraints on the Ly$\alpha$ equivalent width (taken as a lower limit owing to resonant scattering), [C III]λ1907+[C IV]λ1909 equivalent width (for EGS-zs8-1 and EGS-zs8-2), and broadband F125W, F140W, F160W and IRAC 3.6μm and 4.5μm fluxes. We obtain as output the posterior probability distributions of the above free model parameters, as well as those of a large collection of derived parameters, such as for example the production rate of hydrogen ionizing photons per 1500 Å luminosity, $\zeta_U$ (Table 3). The $\zeta_U$ values correspond to the intrinsic UV emission from the stellar population model that reproduces the data, computed before reprocessing by gas and before attenuation by dust. Below we also present $\zeta_{\text{ism}}$, which is computed considering the UV emission after it has been reprocessed by gas and attenuated by dust. This latter quantity provides the total Lyman continuum production rate given the observed far-UV emission.

The modeling procedure is able to successfully reproduce the broadband SEDs of the Roberts-Borsani et al. (2016) galaxies (i.e., Figure 4). Matching the large flux excess in the IRAC [4.5] filter requires models with very large specific star formation rates (7-24 Gyr$^{-1}$), indicating a population undergoing rapid stellar mass growth. The implied interstellar metallicities are in the range $Z=0.0016-0.0026$, which is equivalent to 0.10-0.17 Z$_\odot$ using the solar metallicity value ($Z_{\odot}$=0.01524) from Bressan et al. (2012). The strong [C II], [C III], [C IV] emission in EGS-zs8-1 forces the models to low metallicity (0.11 Z$_\odot$) and significantly reduces the allowable metallicity range. Because of the depletion of metals onto dust grains (parameterized by the $\xi_d$ parameter) the gas-phase metallicity will be lower than the total interstellar metallicity that is fit by the models and reported in Table 3. After accounting for the derived $\xi_d$ values using the method described in Gutkin et al. (2016, in prep), the gas-phase oxygen abundance is found to range between 12+log O/H = 7.76, 7.77, 7.97 for COS-zs7-1, EGS-zs8-1, EGS-zs8-2, respectively. The detection of [C II], [C III] in the spectrum of EGS-zs8-1 allows us to consider variations in the C/O abundance.
We fit the broad-band fluxes and emission lines equivalent widths with the two different set of models corresponding to C/O$_{⊙}$ and 0.52 C/O$_{⊙}$. A visual analysis of the maximum-a-posteriori SED, and a comparison of the Bayesian evidence obtained with the two settings, indicates a slight preference of the model corresponding to 0.52 C/O$_{⊙}$, which exhibits a (marginally) larger sSFR, and a lower metallicity than the model with Solar-scaled C/O. The values reported in Table 3 thus correspond to the sub-Solar C/O models.

As expected for galaxies dominated by such young and sub-solar stellar populations, the models suggest very large Lyman continuum photon production efficiencies, log$_{10}$ ξ$_{ion}$ [erg$^{-1}$Hz] ∼ 25.6, indicating that these galaxies have intense radiation fields. The ξ$_{ion}$ values are larger than canonical values commonly used in reionization calculations (e.g., [Kuhlen & Faucher-Giguère 2012, Robertson et al. 2015, Bouwens et al. 2015a]), and are also larger than the average ionizing photon production efficiencies (log$_{10}$ ξ$_{ion}$ [erg$^{-1}$Hz] = 25.3) recently derived in Bouwens et al. (2015c) for galaxies at 3.8 < z < 5.0 (Figure 5) and the average values derived at z = 2.2 (log$_{10}$ ξ$_{ion}$ [erg$^{-1}$Hz] = 24.77) by Matthee et al. (2016).

If the extreme optical line emission of the RB16 galaxies is typical at z > 7, it would indicate that reionization-era systems likely have considerably larger ξ$_{ion}$ values than previously thought, easing requirements on the escape fraction of ionizing radiation (e.g., Robertson et al. 2015, Bouwens et al. 2015a). The estimated values of ξ$_{ion}$ are in the range log$_{10}$ ξ$_{ion}$ [erg$^{-1}$Hz] = 25.60 and 25.73 for the three galaxies, larger than ξ$_{ion}$ because of the effect of dust attenuation which lowers the observed UV flux density.

5 HIGH FRACTION OF LY$_{α}$ EMISSION AT Z > 7: A NEW POPULATION?

The detection of Ly$_{α}$ in COS-zs7-1 and EGS-zs8-2 establishes that all four of the galaxies identified in RB16 exhibit Ly$_{α}$ in emission, in spite of being situated at redshifts where the IGM is expected to be partially neutral. Of the four Ly$_{α}$ emitters, two have W$_{Lyα} > 25$ Å, implying a large Ly$_{α}$ fraction (ξ$_{Lyα} = 0.50 +0.35$ with W$_{Lyα} > 25$ Å). We search previous spectroscopic studies (e.g., Ono et al. 2012, Schenker et al. 2012, Finkelstein et al. 2013, Schenker et al. 2014, Pentericci et al. 2014) for galaxies with photometric redshifts above z ∼ 7 that are both luminous (M$_{UV} < -21$) and have IRAC fluxes indicative of intense [OIII] + Hβ emission in the 4.5μm filter ([3.6] − [4.5] > 0.5). Only two sources satisfy these requirements (most systems are either too faint or lack IRAC photometry), a z = 7.508 galaxy reported in Finkelstein et al. (2013) and a z = 7.213 galaxy confirmed in Ono et al. (2012). Both show Ly$_{α}$ emission, but only the z = 7.213 emitter has a rest-frame equivalent width in excess of 25 Å.

Together with the RB16 sam-

---

2 [Tilvi et al. 2016] have recently presented detection of Ly$_{α}$ in the z = 7.508 galaxy with the WFC3/IR grism as part of the FIGS survey (Malhotra et al. 2016, in prep). The measured Ly$_{α}$ flux (1.06 × 10$^{-17}$ erg cm$^{-2}$ s$^{-1}$) and rest-frame equivalent width (46.9 Å) are both larger than in the

---

Table 3. Results from photoionization modeling using BEAGLE tool. The quoted uncertainties correspond to the 68% central credible interval.
This implies a high Lyα fraction \( x_{\text{Ly} \alpha} = 0.50 \pm 0.29 \) with \( W_{\text{Ly} \alpha} > 25 \text{ Å} \). Although this conclusion appears at odds with previous studies at \( 7 < z < 8 \) (Figure 9), the average UV luminosity of the six galaxies with Lyα emission \( (M_{\text{UV}} = -21.9) \) is larger than that of the galaxies in the luminous bin of the Schenker et al. (2014) measurements, possibly indicating that Lyα transmission may be enhanced in these ultra-luminous systems.

The detection of UV metal lines allows us to begin exploring the precise physical mechanisms by which Lyα is able to escape so effectively from the luminous RB16 galaxies. In §5.1, we consider whether the pre-selection of galaxies with IRAC 4.5 µm flux excesses is likely to influence the Lyα detection rate, and in §5.2, we use the systemic redshift provided by [CII], C III] to explore whether the Lyα velocity offsets of luminous galaxies boost the transmission of Lyα through the IGM. We will argue that the selection of galaxies with IRAC color excess maximizes the production rate and transmission of Lyα through the local circumgalactic medium, while the identification of the brightest \( z > 7 \) galaxies picks out sources which are most likely to transmit Lyα through the IGM.

5.1 Impact of local radiation field on Lyα equivalent widths

The IRAC 4.5µm flux excesses of the RB16 sample are suggestive of extreme optical line emission. Photoionization models indicate that the data require very large specific star formation rates, moderately low metallicity, and large \( \xi_{\text{ion}} \) (Table 3), suggesting efficient LyC production rates. The distribution of neutral hydrogen in the circumgalactic medium could be very different in such young, rapidly growing systems. Conceivably both the intense radiation field and enhanced stellar feedback of the RB16 galaxies could disrupt the surrounding distribution of gas, reducing the covering fraction of neutral hydrogen and boosting the transmission of Lyα. If the escape fraction of Lyα through the galaxy is indeed related to the specific star formation rate and \( \xi_{\text{ion}} \), we should detect evidence of a larger Lyα emitter fraction in extreme optical line emitters located just after reionization \( (4 < z < 6) \).

To test the connection between Lyα and \( \xi_{\text{ion}} \), we investigate the Lyα equivalent width distribution in a large sample of \( 4 < z < 6 \) galaxies described in our earlier work (Stark et al. 2010, 2011, 2013). Redshifts were obtained via a large survey of UV-selected dropouts in GOODS-N using DEIMOS on Keck II (for details see Stark et al. 2010) and through a VLT/FORS survey described in by Vanzella et al. (2009). Our goal is to determine whether Lyα equivalent widths tend to be enhanced in the subset of \( 4 < z < 6 \) galaxies with extreme optical line emission. At \( 3.8 < z < 5.0 \), it is possible to characterize rest-optical line emission using a similar IRAC flux excess technique as employed by RB16. In this redshift range, the Hα line is situated in the IRAC 3.6 µm filter, while the [4.5] band is free of strong emission lines (e.g. Shim et al. 2011, Stark et al. 2013). While not identical to the RB16 selection (which identifies [OIII]+Hβ emission), the subset of galaxies with extreme Hα emission is similar in nature to those with extreme [OIII]+Hβ emission (Schenker et al. 2013).

In Stark et al. (2013), we measured Hα equivalent widths for a sample of spectroscopically confirmed galaxies at \( 3.8 < z < 5.0 \). Tang et al. (2016, in preparation) provide updated Hα equivalent width measurements for the \( 3.8 < z < 5.0 \) sample with spec-
trosopic constraints (including galaxies with and without redshift confirmations), making use of new high S/N near-infrared photometry from CANDELS and improved IRAC flux measurements, both extracted from catalogs provided in [Skelton et al. (2014)]. Using this new catalog of 3.8 < z < 5.0 Hα measurements, we select those galaxies with IRAC [3.6] flux excesses indicative of Hα+[NII]+[SII] rest-frame equivalent widths in excess of 600 Å. This value is chosen by converting the [OIII]λH/β threshold of the Roberts-Borsani et al. (2016) selection (W_{5000}=[OIII]+[SII]=900 Å) to an Hα+[NII]+[SII] equivalent width using the Anders & Fritze-v. Alvensleben (2003) models with metallicity 0.2 Z⊙. We identify thirty galaxies that satisfy this criterion. In order to robustly compute a Lyα fraction, the sample includes galaxies regardless of whether we successfully confirmed a redshift. To ensure the photometric subset is as reliable as possible, we follow previous studies (i.e. Smit et al. 2015b) and only include those galaxies with photometric redshifts that are confident within the 3.8 < z < 5.0 redshift window. Further details are included in Tang et al. (2016, in preparation). The median UV luminosity and spectroscopic (photometric) redshift of this subset of galaxies are M_{UV} = −20.6 and 4.28±4.23, respectively. We find that ten of thirty galaxies identified by this selection have W_{Lyα} in excess of 25 Å, implying a Lyα emitter fraction of x_{Lyα,25} = 0.33±0.11. This is significantly greater than the Lyα emitter fraction of the full population of similarly luminous galaxies at z = 4 (0.12±0.03) determined in Stark et al. (2011) and is significantly greater than that of galaxies with lower equivalent width Hα emission (Tang et al. 2016, in preparation). If we limit the extreme Hα emitter sample to galaxies with UV continuum slopes that are similarly blue (β < −1.8) as galaxies at z > 7, we find an even larger Lyα emitter fraction (x_{Lyα,25} = 0.53±0.17). These results suggest that Lyα equivalent widths are boosted in galaxies with large equivalent width Hα emission, reflecting either enhanced transmission or production of Lyα photons in galaxies with large sSFR.

A similar trend is seen in the faint gravitationally-lensed z ≈ 1.5 − 3 galaxies described in Stark et al. (2014). While the galaxies are much lower in stellar mass than the RB16 sample, they have similarly large specific star formation rates. Five galaxies have constraints on both [OIII]+H/β equivalent widths and Lyα emission. The [OIII]+H/β equivalent widths of this subset are comparable to those in the RB16 galaxies, ranging from 660 Å to 1620 Å. The rest-frame Lyα equivalent widths of the five galaxies are also extremely large, ranging from 36 to 164 Å, with a median of 73 Å.

The results described above suggest that prominent Lyα emission (W_{Lyα} > 25 Å) is common in UV-selected galaxies with extreme optical line emission, suggesting a connection between the local radiation field and the escape of Lyα from the galaxy. This could reflect both enhanced Lyα transmission (through the circumgalactic medium of the galaxy) and an unusually efficient Lyα production rate in systems with large specific star formation rates. Based on these results, it is not surprising that a sample selected to have extreme optical line emission at z > 7 is found to have larger-than-average Lyα equivalent widths at any given redshift. But unlike the z = 1.5 − 5 galaxies described in this subsection, the RB16 systems are located at redshifts where the IGM is expected to be significantly neutral. While the transmission through the galaxy may be enhanced in the RB16 sample, it is not clear that the local radiation field is sufficient to boost transmission through the IGM. One possibility, suggested in Zirm et al. (2015), is that the identification of the four most luminous z > 7 galaxies in the CANDELS fields picks out overdense regions which have the largest ionized bubbles at any given redshift. In the following subsection, we show that a correlation between Lyα velocity offsets and luminosity is likely to also contribute to the enhanced transmission of Lyα in the four RB16 galaxies.

5.2 Impact of M_{UV} and Δν_{Lyα} on Lyα transmission at z > 7

The velocity offset of Lyα (∆ν_{Lyα}) plays an important role in regulating the transmission of the line through the IGM at z > 6. The larger the velocity offset from systemic, the further away Lyα will be from resonance by the time the line photons encounter intergalactic hydrogen. The attenuation provided by the IGM to Lyα will thus be minimized in galaxies with large velocity offsets. Knowledge of the typical velocity offsets of reionization-era galaxies is thus an important input for mapping the evolving Lyα counts to a neutral hydrogen fraction.

Unfortunately measurement of Lyα velocity offsets in the reionization era is extremely challenging. Not only is Lyα difficult to detect, but the standard rest-optical emission lines ([OIII], Hα) used to constrain the systemic redshift are not observable from the ground. Erb et al. (2014) have recently characterized the Lyα velocity offsets for a large sample of galaxies at z ≈ 2 − 3, where [OIII] and Hα can be easily detected with multi-object near-infrared spectrographs. The results reveal several important relationships. The velocity offset is correlated with UV luminosity and velocity dispersion (at >3σ significance), and is anti-correlated with Lyα equivalent width (at 7σ significance). The smallest velocity offsets are thus found in low luminosity galaxies (Figure 7) with small velocity dispersions and large Lyα equivalent widths. Erb et al. (2014) suggest a scenario where the Lyα profile is modulated by the properties of the gas at the systemic redshift. The small values of Δν_{Lyα} in low mass galaxies could reflect less developed gaseous disks (resulting in less neutral hydrogen at line center) and a harder radiation field capable of reducing the covering fraction of neutral gas at the systemic redshift.

The correlations described above provide a valuable baseline for predicting the likely range of Lyα velocity offsets expected in the reionization era. Since galaxies at z ≠ 0 tend to have larger Lyα equivalent widths (Ouchi et al. 2008, Stark et al. 2011, Curtis-Lake et al. 2012, Cassata et al. 2015) and lower luminosities (McLure et al. 2013, Bouwens et al. 2015b, Finkelstein et al. 2015), smaller Lyα velocity offsets are likely to be common in the reionization era. Measurement of Lyα velocity offsets in a small sample of galaxies at 3.1 < z < 3.6 (Schenker et al. 2013) provided the first evidence of redshift evolution in Δν_{Lyα} at z > 2 (Figure 8). Most recently, Stark et al. (2015d) used the systemic redshift from detection of CIII]λ1909 in a a low luminosity (M_{UV} = −19.3) z = 6.024 galaxy to provide the first constraint on the Δν_{Lyα} at z > 6. The measurement revealed a very small Lyα offset (∆ν_{Lyα} = 120 km s^{-1}), consistent with the trend reported in Schenker et al. (2013).

Such evolution could be driven by the emergence of harder radiation fields and the gradual disappearance of ordered gaseous disks, both of which would reduce the neutral hydrogen content at the systemic redshift. If the tentative indications of evolution in Δν_{Lyα} are confirmed with future observations, it would require less intergalactic hydrogen to explain the disappearance of Lyα emitters at z > 6 (Mesinger et al. 2013). In particular, Choudhury et al. (2015) have recently shown that the evolving Lyα fraction constraints can be fit with neutral fractions of ≳ 30(50)% at z ≈ 7(8) if the average Lyα velocity offset decreases as (1+z)^{-3} at z > 6.

The connection between Δν_{Lyα} and IGM transmission is likely to be very different for the luminous RB16 sample. If the correlations discovered in Erb et al. (2014) are already in place at
z ≃ 7−8, the velocity offsets will be larger, boosting the transmission of Lyα through the IGM. The discovery of a 340 km s\(^{-1}\) velocity offset in EGS-zs8-1 (see §3.1) is consistent with this framework (Figure 7), suggesting that the most luminous galaxies at z > 7 may have enough neutral gas at their systemic redshift to modulate the Lyα profile. Additional support for the existence of a relationship between \(M_{\text{UV}}\) and \(\Delta v_{\text{Ly}\alpha}\) in the reionization era comes from the discovery of large velocity offsets (\(\Delta v_{\text{Ly}\alpha} = 430, 504 \text{ km s}^{-1}\)) in two of the most luminous galaxies known at z ≃ 6 (Willott et al. 2015). Further data are clearly required to determine the relationship between \(\Delta v_{\text{Ly}\alpha}\) and \(M_{\text{UV}}\) at z ≃ 6, yet the first results suggest a scenario whereby large velocity offsets of luminous galaxies allow Lyα to be more easily transmitted through the surrounding IGM. Since luminous systems are also likely to trace overdense regions within large ionized bubbles, the likelihood of detecting Lyα should be considerably greater in the most luminous galaxies at z > 6. Evidence for luminosity-dependent evolution of LAEs at z > 6 has been suggested in previous Lyα fraction studies (e.g., Ono et al. 2012) and is also consistent with the lack of evolution at the bright end of the Lyα luminosity function over 5.7 < z < 6.6 (e.g., Matthee et al. 2015).

6 SUMMARY

We present new Keck/MOSFIRE spectroscopic observations of three of the four luminous z > 7 galaxies presented in Roberts-Borsani et al. (2016). The galaxies are selected to have a large flux excess in the [4.5] IRAC filter, indicative of intense [OIII]+Hβ emission. Previous spectroscopic follow-up has revealed Lyα emission in two of the four galaxies and a tentative detection in a third system. Our new MOSFIRE observations confirm that Lyα is present in the entire sample. We detect Lyα emission in the galaxy COS-zs7-1, confirming its redshift as z\(_{\text{Ly}\alpha} = 7.154\), and we detect Lyα in EGS-zs8-2 at z\(_{\text{Ly}\alpha} = 7.477\), verifying the lower S/N detection presented in Roberts-Borsani et al. (2016).

The ubiquity of Lyα emission in this photometric sample is puzzling given that the IGM is expected to be significantly neutral over 7 < z < 9. To investigate the potential implications for reionization, we have initiated a campaign to target UV metal line emission in the four Lyα emitters. We present the detection of very large equivalent width [CIII], CIII\(\lambda\lambda 977,1909\)\ Å emission in EGS-zs8-1 (W\(_{\text{CIII},0} = 22 \pm 2\) \ Å), a galaxy previously shown by Oesch et al. (2015) to have Lyα emission at z = 7.73. The centroid of CIII\(\lambda\) reveals that Lyα is redshifted from systemic by 340\(\pm 15\) km/s. This velocity offset is larger than that commonly found in less luminous systems and suggests that a correlation between velocity offset and luminosity, known to exist at z ≃ 2 (Erb et al. 2014), may already be in place in the reionization era. Physically, the velocity offset is modulated by the properties of neutral hydrogen at the systemic redshift of the galaxy. The existence of large velocity offsets at z > 6 suggests that a substantial amount of gas has already accumulated at the line center in the most massive galaxies, forcing Lyα to escape at redder wavelengths. We consider the requirements to match the broadband SEDs and UV metal line properties of the Roberts-Borsani et al. (2016) galaxies using the new BEAGLE tool (Chevallard & Charlot 2016). The red IRAC colors require the presence of an hard ionizing spectrum (log\(_{10}\) \(\xi_{\text{ion}}\) ≃ 25.6) in all of the galaxies, while the detection of intense [CIII], CIII emission in EGS-zs8-1 additionally requires models with reasonably low metallicity (0.11 Z\(_{\odot}\)).

These initial results provide the context for understanding why Lyα appears so frequently in the luminous sample of galaxies discovered in Roberts-Borsani et al. (2016). The observability of Lyα at z > 7 depends on the transmission through both the galaxy and the IGM. We argue that the product of both quantities is maximized.
in the RB16 sample. The pre-selection of galaxies with extremely large equivalent width [OIII]+Hβ emission picks out systems with very massive, young stellar populations. Based on results at lower redshift, we suggest that the hard radiation field of these galaxies likely increases the production rate of Lyα and may also decrease the covering fraction of neutral hydrogen in the circumgalactic medium, boosting the transmission of Lyα through the galaxy. However, unlike at lower redshifts, the Lyα emission produced by the RB16 galaxies must traverse a partially neutral IGM. The correlation between the Lyα velocity offset and luminosity offers the explanation for why Lyα is able to escape so effectively through the IGM from this luminous population of z > 7 galaxies. For the typical low luminosity systems in the reionization era, Lyα emerges close to line center and is thus strongly attenuated by the IGM. But for the most luminous systems with substantial velocity offsets, Lyα will be redshifted further into the damping wing by the time it encounters intergalactic HI, enhancing the transmission through the IGM. The escape of Lyα will be further amplified if luminous systems trace overdense regions situated in large ionized bubbles (e.g., Furlanetto et al. 2004). As a result, the disappearance of the Lyα emitter population may well be less pronounced in the most luminous (i.e., MUV = −22) galaxies in the reionization era.

ACKNOWLEDGMENTS
