Charge and spin density distributions are studied within a nano-ring structure endowed with Rashba and Dresselhaus spin orbit coupling (SOI). For a small number of interacting electrons, in the presence of an external magnetic field, the energy spectrum of the system is calculated through an exact numerical diagonalization procedure. The eigenstates thus determined are used to estimate the charge and spin densities around the ring. We find that when more than two electrons are considered, the charge-density deformations induced by SOI are dramatically flattened by the Coulomb repulsion, while the spin density ones are amplified.

I. INTRODUCTION

The possibility of controlling the flow of the electron spins in semiconductor structures by external electric means through spin-orbit interaction (SOI) has dominated the recent past of spintronics research. This fundamental principle, first explored in the Datta-Das spin transistor configuration, has been guiding a sustained effort in understanding all the phenomenological implications of this interactions on systems of electrons. The coupling between spin and orbital motion results either from the two-dimensional confinement (Rashba) or from the inversion asymmetry of the bulk crystal structure (Dresselhaus). The usual expression of the the spin-orbit Hamiltonian $H_{SO}$ retains only the linear terms in the electron momentum $p = (p_x, p_y)$ and is given by

$$H_{SO} = \frac{\alpha}{\hbar} (\sigma_x p_y - \sigma_y p_x) + \frac{\beta}{\hbar} (\sigma_z p_x - \sigma_y p_y).$$

The Rashba and Dresselhaus coupling constants are $\alpha$ and $\beta$, respectively, while $\sigma_{x,y,z}$ are the Pauli matrices. In general, the two interactions are simultaneously present and often have comparable strengths. While $\alpha$, the coupling constant of the Rashba interaction, can be modified by external electric fields induced by external gates, the strength of the Dresselhaus SOI, $\beta$, is fixed by the crystal structure and by the thickness of the quasi two-dimensional electron system. In many situations of interest, an additional energy scale is introduced by the Zeeman interaction of the electron spin with an external magnetic field, proportional to the effective gyromagnetic factor, $g^*$, which depends on the material energy-band structure. While $g^* = -0.44$ is very small in GaAs, it can be more than 100 times larger in InSb.

The interplay between the two types of SOI, which have competing effects on the precession of the electron spin as they rotate in opposite directions, and the Zeeman splitting, which minimizes the energy by aligning the spin parallel to the external field, determines the ground state polarization of the electron system and the characteristics of spin transport. The investigation of such problems in mesoscopic rings has been pursued intensively by several authors. In particular, it was noticed that, in the absence of the Coulomb interaction among the electrons, the interference between the Rashba and Dresselhaus precessions relative to the orbital motion, leads to the creation of an inhomogeneous spin and charge distribution around the ring. The charge inhomogeneity created in this situation has a symmetric structure with two maxima and two minima around the ring and will be called here a charge-density deformation (CDD). The effect of the Coulomb interaction on this type of charge distribution has been considered for two electrons. It was obtained that, on account of the electrostatic repulsion, the two electrons become even more localized in the potential minima associated to the CDD, leading to an amplitude increase.

In this work we obtain an estimate of the effect of the Coulomb interaction on the charge and spin distribution associated with $N = 2, 3$ and 4 electrons in a ring with SOI coupling by an exact diagonalization procedure that uses the configuration interaction method. Our results indicate that when the number of electrons increases, the mutual repulsion leads to more uniform charge distribution around the ring, generating a dramatically flattened CDD. In contrast, the spin-density deformation (SDD) is amplified by the Coulomb effects. This can be explained by the appearance of a stronger repulsion between same spin electrons, leading to more favorable spin orientations.

II. THE RING MODEL

The system of interest in our problem is a two-dimensional quantum ring of exterior and interior radii, $R_{ext}$ and $R_{int}$ respectively. The ring is placed in a perpendicular magnetic field $B$ associated in the symmetric gauge with a vector potential $A = B/2(-y,x,0)$. The single-particle Hamiltonian of an electron of momentum $p = (p_x, p_y)$ and spin $\sigma = (\sigma_x, \sigma_y, \sigma_z)$ is given by

$$H = \frac{p^2}{2m_e} + \frac{\mathbf{g} \cdot \mathbf{B}}{2} \sigma_z + V(r).$$

The Hamiltonian is invariant under time reversal, and the electron spin $\sigma$ undergoes precessions relative to the local magnetic field $\mathbf{B}$, Hamiltonian $H_{SO}$ retains only the linear terms in the electron momentum $p = (p_x, p_y)$ and is given by

$$H_{SO} = \frac{\alpha}{\hbar} (\sigma_x p_y - \sigma_y p_x) + \frac{\beta}{\hbar} (\sigma_z p_x - \sigma_y p_y).$$

The Rashba and Dresselhaus coupling constants are $\alpha$ and $\beta$, respectively, while $\sigma_{x,y,z}$ are the Pauli matrices. In general, the two interactions are simultaneously present and often have comparable strengths. While $\alpha$, the coupling constant of the Rashba interaction, can be modified by external electric fields induced by external gates, the strength of the Dresselhaus SOI, $\beta$, is fixed by the crystal structure and by the thickness of the quasi two-dimensional electron system. In many situations of interest, an additional energy scale is introduced by the Zeeman interaction of the electron spin with an external magnetic field, proportional to the effective gyromagnetic factor, $g^*$, which depends on the material energy-band structure. While $g^* = -0.44$ is very small in GaAs, it can be more than 100 times larger in InSb.

The interplay between the two types of SOI, which have competing effects on the precession of the electron spin as they rotate in opposite directions, and the Zeeman splitting, which minimizes the energy by aligning the spin parallel to the external field, determines the ground state polarization of the electron system and the characteristics of spin transport. The investigation of such problems in mesoscopic rings has been pursued intensively by several authors. In particular, it was noticed that, in the absence of the Coulomb interaction among the electrons, the interference between the Rashba and Dresselhaus precessions relative to the orbital motion, leads to the creation of an inhomogeneous spin and charge distribution around the ring. The charge inhomogeneity created in this situation has a symmetric structure with two maxima and two minima around the ring and will be called here a charge-density deformation (CDD). The effect of the Coulomb interaction on this type of charge distribution has been considered for two electrons. It was obtained that, on account of the electrostatic repulsion, the two electrons become even more localized in the potential minima associated to the CDD, leading to an amplitude increase.

In this work we obtain an estimate of the effect of the Coulomb interaction on the charge and spin distribution associated with $N = 2, 3$ and 4 electrons in a ring with SOI coupling by an exact diagonalization procedure that uses the configuration interaction method. Our results indicate that when the number of electrons increases, the mutual repulsion leads to more uniform charge distribution around the ring, generating a dramatically flattened CDD. In contrast, the spin-density deformation (SDD) is amplified by the Coulomb effects. This can be explained by the appearance of a stronger repulsion between same spin electrons, leading to more favorable spin orientations.
p = −iℏ∇ + eA and effective mass m* is written as the sum of an orbital term \( H_O = p^2/2m^* \), a Zeeman contribution \( H_Z = (1/2)g^*B\sigma_z \), and the spin-orbit coupling given in Eq. (1). The ensuing expression, 

\[
H = H_O + H_Z + H_{SO},
\]

is discretized in a standard manner on a grid defined by \( N_r \) radial and \( N_\phi \) angular sites, as shown in Fig. 1. The radial coordinate of each site is \( r_k = R_{ext} - (k - 1)\delta r \), with \( k = 1, 2, \ldots, N_r \), while \( \delta r = (R_{ext} - R_{int})/(N_r - 1) \) is the distance between adjacent sites with the same radius. Similarly, the angular coordinate is \( \phi_j = (j - 1)\delta \phi \), where \( j = 1, 2, \ldots, N_\phi \) and \( \delta \phi = 2\pi/N_\phi \) is the angle between consecutive sites with the same radius. The Hilbert space is spanned by the ket-vectors \( |k\sigma\rangle \), where the first integer, \( k \), stands for the radial coordinate, the second one, \( \sigma \), for the angular coordinate, and \( \sigma = \pm 1 \) denotes the spin projection in the \( z \) direction.

In this basis \( \{ |k\sigma\rangle \} \), the matrix elements of the orbital Hamiltonian are given by:

\[
\langle k\sigma|H_O|k'\sigma'\rangle = T\delta_{\sigma\sigma'} \left\{ t_\sigma + t_r \left[ \frac{1}{2}B \left( \frac{r_k}{4R_{ext}} \right)^2 \right] \delta_{kk'}\delta_{jj'} - t_\sigma \frac{i}{4\delta \phi} \delta_{kk'}\delta_{jj' + 1} + t_r \delta_{kk'}\delta_{jj'} \right\} + h.c. \quad (3)
\]

\( T = \hbar^2/(2m^* R_{ext}^2) \) is the energy unit, while \( R_{ext} \) is the length unit. In \( T \) units, we obtain \( t_\sigma = [R_{ext}/(r_k\delta \phi)]^2 \) the angular hopping energy, \( t_r = (R_{ext}/\delta r)^2 \) the radial hopping energy, and \( t_B = \hbar eB/(m^*T) \) the magnetic cyclotron energy. (\( h.c. \) denotes the Hermitian conjugate.)

In the same basis, the Zeeman Hamiltonian is simply diagonal in the spatial coordinates,

\[
\langle k\sigma|H_Z|k'\sigma'\rangle = \frac{1}{2}Tt_B\gamma \langle \sigma_z \rangle \delta_{kk'}\delta_{jj'}, \quad (4)
\]

where \( \gamma = g^*m^*/(2m_e) \) is the ratio between the Zeeman gap and the cyclotron energy, \( m_e \) being the free electron mass.

For the spin-orbit Hamiltonian we obtain:

\[
\langle k\sigma|H_{SO}|k'\sigma'\rangle = \frac{1}{2}Tt_\alpha \left[ \frac{r_k}{4R_{ext}} \langle \sigma_j^2 \rangle \delta_{kk'}\delta_{jj'} \right. + it^{1/2} \left( \langle \sigma_j^3 \rangle + \langle \sigma_j^{3*} \rangle \right) \delta_{kk'}\delta_{jj' + 1} - it^{1/2} \left( \langle \sigma_j^3 \rangle \delta_{kk'}\delta_{jj'} + 1 \right) \delta_{jj'} \right] + Tt_\beta \sum_{k,j} \left[ \sigma_j \rightarrow \langle \sigma_j \rangle^* \right. + \left. \langle \sigma_j \rangle^* \right] + h.c. \quad (5)
\]

where \( t_\alpha = \alpha/(R_{ext}T) \) and \( t_\beta = \beta/(R_{ext}T) \) are the two types of spin-orbit relative energies, while \( \sigma_j(r,\phi) = \sigma_x \cos \phi + \sigma_y \sin \phi \) and \( \sigma_j(\phi) = -\sigma_x \sin \phi + \sigma_y \cos \phi \) are the radial and angular Pauli matrices, respectively. We used the slightly shorter notations \( \sigma_j^2 = \sigma_r(\phi) \) and \( \sigma_j^2 = \sigma_\phi(\phi) \) for the matrices at the particular angles on our lattice. The Rashba spin-orbit terms are all included in the first square bracket. The Dresselhaus terms are very similar to the Rashba ones, being given by the substitutions indicated in the second square bracket.

The single particle states of the noninteracting Hamiltonian, \( H\psi_a = \epsilon_a \psi_a \), are computed as eigenvalues and eigenvectors of the matrices \( \sum_{a} \psi_a(k,j) |\sigma\rangle \), where \( \Psi_a(k,j) = \sum_{a} \psi_a(k,j) |\sigma\rangle \) are c-numbers.

In the basis provided by \( \{ |a\rangle \} \), the interacting many-body Hamiltonian is written in the second quantization as

\[
H = \sum_a \epsilon_a c_a^\dagger c_a + \frac{1}{2} \sum_{abcd} V_{abcd} c_a^\dagger c_b^\dagger c_d c_c, \quad (6)
\]

where \( c_a^\dagger \) and \( c_a \) are the creation and annihilation operators on the single-particle state \( a \). The matrix elements of the Coulomb potential \( V(r - r') = e^2/(\kappa |r - r'|) \), \( \kappa \) being the dielectric constant of the material, are in general given by

\[
V_{abcd} = \langle \psi_a(r)\psi_b(r')|V(r - r')|\psi_c(r)\psi_d(r') \rangle. \quad (7)
\]

In the present discrete model the double scalar product is in fact a double summation over all the lattice sites and spin labels

\[
V_{abcd} = TtC \sum_{kj} \Psi_{a,\sigma}(k) \Psi_{b,\sigma'}(k') \frac{R_{ext}}{|r_{j} - r_{j'}|} \times \Psi_{c,\sigma}(k) \Psi_{d,\sigma'}(k') \quad (8)
\]
The new energy parameter introduced by the Coulomb repulsion is \( t_C = e^2/(\kappa R_{\text{ext}} T) \). In the above summation over the sites, the contact terms \((k = k', j = j')\) are avoided, as their contribution vanishes in the continuous limit.

The many-body states \( \Phi_\mu \) are found by solving the eigenvalue problem for the Hamiltonian \( \mathcal{H} \),

\[
\mathcal{H} \Phi_\mu = E_\mu \Phi_\mu .
\]

A potential solution of the equation is written in the configuration interaction representation as a linear combination of the non-interacting system eigenstates \( \{ \psi_{\alpha} \} \)

\[
\Phi_\mu = \sum_\alpha c_{\mu \alpha} |\alpha\rangle , \tag{9}
\]

with \( \{ |\alpha\rangle = |i_1^a, i_2^a, \ldots, i_K^a\rangle \} \) where \( i_a^\alpha = 0, 1 \) is the occupation number of the single-particle state \( \psi_\alpha \) and \( K \) is the number of single-particle states considered. The occupation numbers \( i_K^a \) are listed in the increasing energy order, so \( \epsilon_K \) is the highest energy of the single-particle state included in the many-body basis. For any \( |\alpha\rangle \) we have \( \sum_\alpha i_a^\alpha = N \), which is the number of electrons in the ring. It is straightforward to derive the matrix elements of \( \mathcal{H}_{\alpha\alpha'} \) using the action of the creation and annihilation operators on the many-body basis. In practice Eq. (9) is convergent with \( K \) for a sufficiently small number of electrons, and sufficiently small ratio of Coulomb to confinement energy, \( t_C \). This procedure, also known as "exact diagonalization", does not rely on any mean field description of the Coulomb effects, like Hartree, Hartree-Fock, or DFT.

To be able to carry the numerical calculations in a reasonable amount of time, we choose a small ring of radii \( R_{\text{ext}} = 50 \text{ nm} \) and \( R_{\text{int}} = 0.8 R_{\text{ext}} \), containing \( N \leq 4 \) electrons. The discretization grid has 10 radial and 50 angular points (500 sites), as shown in Fig. 1. Two common semiconductor materials used in the experimental spintronics are used for the selection of the material constants needed: InAs with \( m^* = 0.023 m_e \), \( \gamma^* = -14.9 \), \( \kappa = 14.6 \), and estimated (or possible) values for the spin-orbit interactions \( \alpha \approx 20 \) and \( \beta \approx 3 \text{ meVnm} \); InSb with \( m^* = 0.014 m_e \), \( \gamma^* = -51.6 \), \( \kappa = 17.9 \), and \( \alpha \approx 50 \), \( \beta \approx 30 \text{ meVnm} \). The relative energies which we defined are: for InAs \( t_\alpha = 0.60 \), \( t_\beta = 0.09 \), \( t_C = 2.9 \), \( \gamma = -0.17 \); for InSb \( t_\alpha = 0.92 \), \( t_\beta = 0.55 \), \( t_C = 1.5 \), \( \gamma = -0.36 \). In our calculations we have considered material parameters somewhere in between these two sets: \( t_\alpha = 0.7 \), \( t_\beta = 0.3 \), \( t_C = 2.2 \), \( \gamma = -0.2 \).

III. RESULTS

A. Single particle calculations

In the absence of the SOI, \( (\alpha = \beta = 0) \), the single particle Hamiltonian \( H \) shares its eigenstates \( \psi_\alpha \) with the \( \hat{z} \) components of the angular momentum \( L_z \) and spin \( S_z = \hbar \sigma_z/2 \). In the presence of only one type of SOI, either \( \alpha \neq 0 \) or \( \beta \neq 0 \), the Hamiltonian commutes with the \( \hat{z} \) component of the total angular momentum, \( L_z + S_z \), which is conserved. When both \( \alpha \neq 0 \) and \( \beta \neq 0 \), the angular momentum is no longer conserved. However, \( \psi_\alpha \) continue to be eigenstates of the parity operator \( P = \Pi \sigma_z \), \( \Pi \) being the (three dimensional) spatial inversion operator. Indeed, the general Hamiltonian \( H \) commutes with \( P \), which can be easily verified by using \( \Pi \mathbf{p} = -\mathbf{p} \Pi \) and the commutation rules of the Pauli matrices. So in general \( P \psi_\alpha = \pm \psi_\alpha \), and thus the parity \( s = \pm 1 \) of any state \( \alpha \) is conserved, i. e. it is independent on the magnetic field. In particular, when \( \alpha = \beta \) and \( g^* = 0 \), all states become parity-degenerate at any magnetic field. We identify the parity of the single particle states calculated on our discrete ring model by looking at the relation \( \psi_{a,s}(k,j) = s \sigma_\alpha \psi_{a,\bar{s}}(k,j) \) where \( (k,j) \) and \( (k,j) \) are diametrically opposed sites, with angular coordinates \( \varphi_j = \varphi_j + \pi \).

In Fig. 2 we show the single particle states energy for \( 0 < t_B < 10 \) (units of \( T \)), which corresponds to a magnetic field strength between 0 and 1.32 Tesla. Further
increment of the magnetic field requires an augmentation of the number of sites on the ring in order to maintain the discrete model as a reasonable approximation of a physically continuous ring. At zero magnetic field all states are parity degenerate, which is just the ordinary spin degeneracy. The degeneracy is in general lifted by a finite magnetic field. There are, however, some particular values of \( t_B \) where the degeneracy persist. This situation is represented in Fig. 2(a) by all intersection points of two lines corresponding to the two possible parities. Such intersections do not occur between states with the same parity. Due to the spin-orbit coupling, the orbital momentum of one state depends on the spin of the other state and vice versa, and, consequently, states of same parity do in fact interact and thus avoid intersections. Although in Fig. 2(a) many states represented by the same line type apparently cross each other, in reality there are always tiny gaps between them, similar to those visible at \( t_B \approx 2 \) between the first and the second excited states or at \( t_B \approx 5.5 \) between the first, second, and third excited states. The magnitude of these gaps depends on the \( g \)-factor, reducing in size for a smaller \( g^* \) parameter.

In Fig. 2(b) the evolution of the expected spin in the \( z \) direction, \( S_z = \hbar \langle \psi | \sigma_z | \psi \rangle / 2 \) is presented for the first four states in the energy order. One can see how the spin flips for states avoiding the crossing, like those with negative parity at \( t_B \approx 2 \) (dashed and dotted lines in Fig. 2(b)).

Only one type of SOI, either Rashba or Dresselhaus, is sufficient to avoid the crossing of states with the same parity, but in this case the charge and the spin densities are uniform around the ring. When both SOI types are present the charge and spin densities become nonuniform. This situation is equivalent with the presence of a potential with two maxima and two minima around the ring, having reflection symmetry relative to the axes \( y = x \) (or \( \varphi = \pi/4 \), corresponding to the crystal direction \([110] \)) and \( y = -x \) (or \( \varphi = -\pi/4 \), corresponding to the crystal direction \([1\bar{1}0] \) ).

The amplitude of the CDD is illustrated in Fig. 2(c) where the standard deviation (in the statistical sense) \( \Delta_c \) of the charge density calculated around one circle on the ring, close to the mean radius, with radial site index \( k = 6 \), is plotted for the lowest four energy states. The density deformation occurs on account of the two combined SOI types which lead to spin interference and additional interaction between states with the same parity. Consequently, the amplitude of the CDD for a certain state is maximum at those magnetic fields where the parity degeneracy is lifted (the state avoids a crossing with another state of the same parity). In Fig. 2(c) this is clearly seen at \( t_B \approx 2 \), for the excited state. In this example the CDD in the ground state is very weak. The sharp peak at \( t_B \approx 0.4 \) indicates the existence of a narrow gap between the 4-th and 5-th energy states that avoid crossing.

In the following considerations, we will include more than one electron. In Fig. 3 we compare the energy spectra for the first 12 states vs. the magnetic energy for \( N = 2, 3 \), and 4 electrons, without and with Coulomb interaction. Since the Coulomb interaction is invariant at spatial inversion (and independent on spin) the parity \( s \) is also conserved in the many-body states. Spectra drawn for \( t_C = 0 \) and \( t_C = 2.2 \) have similar features. The interacting spectrum presents a shift to higher energies, on account of the additional Coulomb energy, and a slight increase of the gaps at high magnetic fields. Moreover, the crossings and the anti-crossings (points where the crossings were avoided) of the energy levels have a tendency to shift slightly to higher magnetic fields. Similarly, the gap between the ground state and the excited states increases at high \( t_B \).

The total spin \( S_z \) for each of the first three energy states is shown in Fig. 4. At zero magnetic field, for an even number of electrons, here \( N = 2 \) or \( N = 4 \), the ground state is non-degenerate and has total spin \( S_z = 0 \), i.e. the spin-up and spin-down states of individual electrons compensate. When the field is applied, the first spin flip in the interacting ground state, as well as the spin saturation, occur at lower magnetic fields than in the absence of the Coulomb repulsion. This is a result of the mixing of spin states with the same parity produced...
by the interaction. For \( N = 3 \) the ground state is spin (double) degenerate at zero field. In the presence of the Coulomb interaction, the total spin in the ground state is 0 and 1, and the lines showing the excited states are shifted to the right, for clarity.

Next, we investigate the effect of the Coulomb interaction on the spin distribution around the ring. The standard deviation of the spin density projected along the \( z \) direction, \( \Delta_z \), is plotted in Fig. 5, where we show the results calculated as before for the circle corresponding to the sites with radial coordinate \( k = 6 \). The spin density deformation (SDD) is actually amplified by the Coulomb interaction for all \( N = 2, 3, 4 \). As the CDD’s, the SDD’s reach their maximum at the magnetic fields where level repulsion occurs and remains prominent even when the gaps are very small. The Coulomb enhancement is a result of the mixing of states with the same parity, but with different spin orientation produced by the Coulomb potential. Consequently the SDD’s have in general a richer structure than the CDD’s.

Finally, in Fig. 4 we display an example of CDD and SDD, obtained for \( N = 4 \) interacting particles. The

FIG. 4: (Color online) The total spin projection in the \( z \) direction, in units of \( \hbar/2 \), for the many body states with \( N = 2, 3, 4 \) electrons. Without interaction, i. e. \( t_C = 0 \) in panels (a),(c),(e), and with interaction, with \( t_C = 2.2 \), in panels (b),(d),(f). Only the first three states are shown here, the ground state (GS), the 1-st excited states (ES1), and the 2-nd excited state (ES2). The magnetic energy \( t_B \) varies between 0 and 10 and the lines corresponding to the excited states are shifted to the right, for clarity.

FIG. 5: (Color online) The standard deviation \( \Delta_z \) of the charge on the circle \( k = 6 \) around the ring, as a measure of the amplitude of the charge deformation. Shown are the results for the ground state (GS), the 1-st excited states (ES1), and the 2-nd excited state (ES2), for \( N = 2, 3, 4 \) electrons without interaction (\( t_C = 0 \)), and with interaction (\( t_C = 2.2 \)). The amplitude of the CDD’s is strongly reduced by the Coulomb effects for \( N = 3, 4 \); notice the different scales used in the paired panels (c),(d) and (e),(f). The magnetic energy \( t_B \) varies between 0 and 10 and the lines corresponding to the excited states are shifted to the right, for clarity.
charge and spin distributions corresponding to the second excited state and $t_B = 4.5$ are illustrated in Figs. 6(f) and 6(f), respectively. The CDD is weak, but still it has four visible maxima. For two electrons the CDD has only two maxima which are along the directions $x = y$ or $x = -y$, depending on the state and on the magnetic field, both with and without the Coulomb interaction. In particular, for a strictly one-dimensional ring model and $N = 2$, in the ground state, the maxima are always along the line $x = -y^{&frac;3}{2}$ whereas for a two-dimensional model they can also be along $x = y$. But in general, for $N > 2$ electrons, screening effects may distribute the charge in more complicated configurations. Similar profiles with multiple local oscillation may be obtained for the spin density, eventually becoming spin-density waves around the ring.

FIG. 6: (Color online) The standard deviation $\Delta_z$ of the spin projection along the $z$ direction on the circle $k = 6$ around the ring, as a measure of the amplitude of the spin-density wave. Like in the previous figures GS, ES1, and ES2 in the legend indicate the ground state, the 1-st excited states, and the 2-nd excited states, respectively. The results are shown for $N = 2, 3, 4$ electrons without ($t_C = 0$), and with interaction ($t_C = 2.2$). Unlike the CDD’s, the SDD’s are amplified by the Coulomb interactions for all $N$. The magnetic energy $t_B$ varies between 0 and 10 and the lines corresponding to the excited states are shifted to the right, for clarity.

FIG. 7: (Color online) (a) The charge density for $N = 4$ electrons with interaction ($t_C = 2.2$), in the second excited state, i.e. ES2 in Fig. 6(f), with magnetic energy $t_B = 4.5$. (b) The corresponding total spin distribution along the ring $k = 6$ where the standard deviation of the $z$ component is calculated and shown in Fig. 6(f).

IV. CONCLUSIONS

We calculated the many-body states of a system of $N = 2, 3$, and 4 interacting electrons located in a ring of finite width with Rashba and Dresselhaus spin-orbit coupling, in the presence of a magnetic field perpendicular on the surface of the ring. The Coulomb effects are fully included in the calculation via the “exact diagonalization” method. We obtained inhomogeneous charge densities, or CDD’s, around the ring due to the combined effect of the two types of SOI. When the Coulomb interaction is included the charge deformation is amplified for $N = 2$, as also shown by other authors. For $N > 2$ we find that the CDD is dramatically flattened out in the presence of the Coulomb interaction. We interpret the result as a screening effect. On the contrary, the spin inhomogeneities, or SDD’s, are amplified by Coulomb effects for all $N > 1$.
