There have been comparatively few investigations reported of radiation effects in zeolites, although it is known that these materials may be modified substantially by exposure to ionizing radiation. Thus, by exposure to γ-rays or high-energy particles, the charge states of atoms may be changed so to create, and accumulate, lattice point defects, and to form structurally disordered regions. Such a technique may permit the creation, in a controlled fashion, of additionally useful properties of the material while preserving its essential stoichiometry and structure. Accordingly, we present an application, in which the cation-exchange capacity of a natural zeolite (clinoptilolite) is substantially enhanced, for the treatment/decontamination of water contaminated with radionuclides e.g. 134Cs, 137Cs and 90Sr, by its exposure to high-energy (8 MeV) electrons, and to different total doses.

Such a technique may permit the creation, in a controlled fashion, of additionally useful properties of the material while preserving its essential stoichiometry and structure. Accordingly, we present an application, in which the cation-exchange capacity of a natural zeolite (clinoptilolite) is substantially enhanced, for the treatment/decontamination of water contaminated with radionuclides e.g. 134Cs, 137Cs and 90Sr, by its exposure to high-energy (8 MeV) electrons, and to different total doses.

Rarely in our technological society does the discovery of a new class of inorganic materials result in such a wide scientific interest and kaleidoscopic development of applications as has happened with the zeolite molecular sieves”, Donald W. Breck (1974)1. Just some of the manifold applications of zeolites are shown in Fig. 1, the variety and number of which are extended on an annual basis. The study of minerals is a mature science, and a major driving force for investigations of this kind is that, through the understanding of means for their formation, their crystal structure and other salient properties, novel materials may be produced by both a priori and post-synthetic means. Of the broad family of minerals, it is the zeolites which furnish highly effective catalysts, as are used extensively in the petrochemical industry and for other niche applications, e.g. in catalytic convertors, to mitigate local air-pollution from vehicles. The catalytically active sites are located within the internal cavities of a microporous structure, and are associated with cations that are present in sufficient concentration to electrostatically counterbalance the negatively charged, aluminosilicate framework1,2. Many physical and chemical properties of zeolites are determined by the nature and concentrations of those cations that are present in the zeolite unit (elementary) cell.

Zeolites are high-inner-surface-area crystalline materials with an open, three-dimensional “honeycomb” framework consisting of tetrahedral AlO4− and SiO4− units linked through shared oxygen atoms. There are 40 zeolites known to occur naturally, and over 150 versions which have been prepared by synthetic methods. One might visualize the structure of a zeolite by assuming a neutral SiO2 framework and, periodically, making an isomorphous substitution of an AlO2− unit for SiO2. In consequence, the resulting structure bears a net negative charge on each framework aluminum atom. Accordingly, this negative charge is electrostatically counterbalanced by those cations (e.g., Na+, K+, NH4+) which reside in the pores of the framework. A mobility is hence conferred upon them, so that they are available for exchange with other cations, when placed in contact with a solution of them; indeed, the major volume-use of zeolites currently is in cation-exchange applications, e.g. as “builders” in washing powders, to avoid the ecosystem damage caused by polyphosphates, which were formerly used on a large scale for this purpose.

Some critical properties of zeolites are:
The idealized, stoichiometric formula, given to zeolites is: $M_x/n[Al^xSiyO_{2(x+y)}]pH_2O$, where $M$ - (Na, K, Li); (Ca, Mg, Ba, Sr); $n$ - charge of a cation; $y/x = 1-6$; $p/x = 1-4$. The oxide formula of zeolites is: $M_{2/n}Al_2O_3 \cdot xSiO_2 \cdot yH_2O$.

The pore size refers to a two-dimensional “window” within the zeolite structure and is determined by the number of tetrahedral units that are mutually connected. This structure is further extended by connecting the tetrahedral units to form a three-dimensional array, which provides a series of more voluminous internal cavities that are interconnected by the pore openings. In some zeolites there are no cavities at all, but rather, a series of one-, two-, or three-dimensional channels which permeate the structure. In addition, various post-synthetic modifications have been developed, including hydrothermal treatments, coating techniques, by selectively admitting molecules with selected properties, and through molecular impregnation, which serve to provide certain further adjustments to the catalytic and adsorptive characteristics of chosen zeolites.

Of the 40 known designated natural zeolites, the three that are of greatest economic importance are clinoptilolite, mordenite and chabazite. Clinoptilolite presents a unique combination of high cation-exchange capacity, and stability to environmental attrition, rendering it a particularly effective material for the removal of toxic pollutants from water and from soil.

There are about 50 million metric tons of natural clinoptilolite present in different regions of Armenia - the best known being the Noyemberyan region - which may be used in a wide range of applications (Table 1).

Table 1 | General zeolite properties

| Property                  | Range                           |
|---------------------------|---------------------------------|
| Channels                  | 2.2–8 Å                         |
| Cavities                  | 6.6–11.8 Å                      |
| Thermal stability         | 500–1,000 °C                    |
| Ion-exchange capacity     | Up to 700 milliequivalents/100 g|
| Surface area              | Up to 900 m²/g                  |
| Water capacity            | <1 to ~ 25 wt. %                |
| Water affinity            | Hydrophilic to hydrophobic      |

There have been many articles published, concerning both pure and applied aspects, on the zeolite, clinoptilolite\(^3\)\(^-\)\(^4\); however, the use of radiation to modify the properties of zeolites is relatively unreported\(^5\)\(^-\)\(^8\). The present communication focuses on a specific application, which is the employment of an initially irradiated clinoptilolite for the absorption of radioactive cations from aqueous media, as in the...
treatment (“clean-up”) of radioactive wastewater from the Armenian Nuclear Power Plant (ANPP). Indeed, this is one of the first reports of the use of radiation-modified clinoptilolite samples for this purpose, which is shown to be a highly effective material in reducing of the overall radioactivity of the water. Since the liquid radioactive wastes from nuclear power plants (NPP) contain far more cesium than other radioactive elements, our focus is on the removal of this particularly, by sorption into the zeolite cages through cation-exchange, during the cleaning process.

Results
Radioactive wastewater from the Armenian Nuclear Power Plant with a low concentration of Na⁺ and K⁺, was chosen for this investigation. The additional chemical elements present were: Cl⁻ - 0.15 mg/kg, NH₄⁺ - 0.5 mg/kg, Na - 0.15 mg/kg, K - 0.2 mg/kg, B - 12.6 g/L. The initial pH of the solution was 5.9, but this was increased to pH 12 by the addition of aqueous NaOH. The initial radioactivity of the water was: 137Cs – 2.9·10⁴ Bq/L, 134Cs – 2.4·10⁴ Bq/L, 60Co – 4.7·10³ Bq/L.

Semiconductor detectors with a high efficiency were applied to measure the water radioactivity. The average count time of the detector was about an hour at the background level of 30–40 counts/min and the “Genie” program was used. At least 10 different zeolite samples were counted to obtain sufficient statistics and a good correspondence of results (80–90%) was found. The three columns system applied (Fig. 2) in these experiments proved to be a useful and efficient laboratory installation. In order to determine the efficiency of the entire 3-column installation, all 3 columns were connected consecutively: described as columns N, 1, 2, 3.

Typical values are presented in the Tables 2, 3 below and also graphically in Fig. 3. The water radioactivity was determined following each cycle after passing through the 3 columns of the installation. Each measurement was repeated some 8–10 times to ensure statistical consistency. Electron-irradiation of each zeolite sample was performed at five different doses, totaling around 100 separate experiments.

The reduction of radioactivity from ANPP waste water by means of electron irradiated clinoptilolite, as a function of the degree of electron irradiation (dose) is presented in Fig. 4 for the principal radionuclides: 134Cs, 137Cs and 60Co. The results show the absorption of radioactive cations as is specified for the prevailing degree of radiation modification, and which, at a maximum, corresponds to a reduction in radioactivity from 137Cs by a factor of more than 800 and 134Cs by a factor of more than 1750, indicating that an isotope fractionation operates and which serves to preferentially absorb the lighter isotope. Accordingly, the maximum initial radioactivity of the water was 2.9·10⁴ Bq/L, but after processing this was reduced to 30 Bq/L. This may be compared with the acceptable level for which water may be employed in technical applications, i.e. 3 Bq/L. When the untreated (non irradiated) zeolite was used, the reduction in the radioactivity level of the water was reduced by a similar factor to that reported in the literature. However, while the different degrees of reduction (72 for 137Cs and 75 for 134Cs) indicate that an isotope fractionation serves for the untreated clinoptilolite samples, it is clear that the effect is markedly enhanced when the zeolite is modified by the radiation treatment.

Discussion
From the results obtained for cleaning radioactive wastewater from the ANPP (summarized in Fig. 4), it is clear that the radiation modification of clinoptilolite leads to a considerable enhancement in its capacity to sorp radioactive cations. This is due to an increase in the sorption capacity at the surface of the zeolite grains, caused by the energy delivered by the radiation. The effect is more pronounced for cations with a higher ionic radius \( r_{\text{Cs}^+} \sim 1.67 \text{ Å}, r_{\text{Ag}^{2+}} \sim 1.44 \text{ Å} \) than for those cations with a smaller ionic radius \( r_{\text{Co}^{3+}} \sim 0.63 \text{ Å}; r_{\text{Ag}^{+}} = 1.13 \text{ Å} \). While another fission radionuclide (I) has a larger ionic radius \( r_{\text{I}^-} = 2.2 \text{ Å} \), it is not sorped into the zeolite by cation exchange, since it carries a negative rather than a positive charge and is effectively repelled by the negatively charged zeolite framework. There are different effects that can occur when zeolites are exposed to radiation, but which may be grouped broadly as (i) ionization (radiolysis) and (ii) atomic displacements by nuclear collisions (“knock on” effects). The latter are expected to contribute more greatly when high-energy radiation is being employed, as in the present study. Thus, radiation shaking, may lead to the removal of different molecular species that were originally contained in the zeolite cage pores, and changes in the charge-states of sub-lattices may occur to provide sites for the capture of radioactive Cs⁺ and other cations. It is likely that part of the mechanism by which the cation-exchange capacity of clinoptilolite toward Cs⁺ is so markedly improved by prior electron-irradiation involves the radiolysis and displacement of water molecules that are entrapped in the zeolite micropores, along with the creation of other point-defects and

![Figure 2](image-url)
(charged) radiation damage centres where Cs\(^{+}\) (along with other radionuclide cations) can be trapped, although there is much to be understood about the process as yet. It was proposed previously that hydroxyl radicals, formed by the radiolysis of water, might be able to break Si-O-Si or Si-O-Al bonds in the zeolite framework, and that the radiolytic production of hydrated protons [H\(^+\)(H\(_2\)O)\(_n\)] can also induce the cleavage of these bonds\(^{15}\). A variety of charged defect centres have also been characterized in zeolites and related materials formed by exposure to radiation of various kinds, e.g. A- and A'-centres (trapped holes on oxygen from Si-O bonds), and B-centres, which are sites where an electron has been captured at an Al-O unit. Positively charged (hole) sites of the type, Si-O\(^{+}\)\(-\)Si and Si-O\(^{+}\)\(-\)Al

have been identified by E.P.R. spectroscopy in irradiated zeolite samples\cite{15}, and a wide range of radical cations formed by charge-transfer from adsorbed organic molecules to the zeolite, have also been characterized\cite{16}. However, the nature of the corresponding electron capture site is less clear\cite{16}. In a recent study, the catalytic performance of the zeolite SSZ-13 was shown to be enhanced by neutron irradiation, in which Si-O-O\textsuperscript{-} peroxyl radicals and nonbridging oxygen hole centres (NBOHC: Si-O\textsuperscript{#}) were identified and are proposed to be the active defects responsible for the catalyst modification\cite{15}. Most noteworthy is the fact that in previous studies of zeolites that were exposed to high-energy electrons, a partial or complete amorphization of the initially crystalline structure occurred, accompanied by a dramatic reduction (by up to 95\%)\cite{13,14} in the cation-exchange and absorption/desorption capacities of the zeolite for radionuclides, such as Cs\textsuperscript{+} and Sr\textsuperscript{2+}. Our present results of an enhanced sorption of Cs\textsuperscript{+} and Sr\textsuperscript{2+} (and significantly so) caused by exposure of high-energy electrons are the exact opposite of this. More comprehensive irradiation dose dependence measurements are necessary to determine the highest possible enhancement parameter.

To obtain further insight into the present case, we have measured the infrared absorption spectra (IR) and the dielectric permittivity (fig. 5) of the irradiated clinoptilolite samples. Fig. 6 shows the variation in the intensity of the $\lambda = 1.91 \mu m$ band as a function of radiation dose, for (i) the zeolite treated with acetic acid, prior to the irradiation, (ii) the untreated zeolite, and (iii) the zeolite treated with aqueous ammonium chloride, prior to the irradiation. The
1.91 μm wavelength corresponds to 5236 cm$^{-1}$ which accords with water residing in the zeolite pores$^{17}$, and we note that when this became a minimum (for irradiation doses of $10^{12}$–$10^{13}$ e/cm$^2$), the intensity of the $\lambda = 2.94$ μm band (3450 cm$^{-1}$) became a maximum. The latter frequency accords with one of the vibrational signatures for free water$^{18}$. We interpret these changes in terms of both ionization and knock on effects on water molecules confined in the zeolite pores. Water molecules can be displaced easily, either by direct collision, or as constituent fragments separated by radiolysis. Thus, the structural water may be either displaced as an intact molecule or in the form of separate ions and radicals.

The intensity of the 1100 cm$^{-1}$ (9 μm) band was observed to decrease and a new absorption band of 830 cm$^{-1}$ (12 μm) appeared to increase following a radiation dose in the region of $10^{13}$ e/cm$^2$. This can probably be attributed to a change in the oxygen state from an interstitial to a lattice site because the irradiation creates many more vacancies of Si and Al atoms and releases new sites for mobile oxygen atoms. The situation resembles the so-called “A-center” in silicon crystals following irradiation, where interstitial oxygen atoms move to silicon atom vacancies generated by irradiation, and then form oxygen (hole) vacancy complexes, which have an IR absorption band at 12 μm (833 cm$^{-1}$).

To understand the effect of electron irradiation on the zeolite framework structure, we assume that in the clinoptilolite crystal sample there is a dominant and sufficient concentration of oxygen atoms ($10^{19}$ cm$^{-3}$–$10^{21}$ cm$^{-3}$) which can form bonds with vacancies (V) or interstitial atoms (I) and also form capture centers:

$$A = (OV) \quad B = (OI),$$

where V, I are Si and Al vacancy interstitials, respectively, O is the oxygen atom. The concentration of V or I is defined by the irradiation dose:

$$N_{I,V} = \sigma N_0 \phi,$$

where $\sigma$ is the probability (cross section) of defect production (cm$^2$), $N_0$ is the concentration of Si or Al atoms (cm$^{-3}$) in clinoptilolite, and $\phi$ is the irradiation dose (cm$^{-2}$). Since the ratio of SiO$_2$/Al$_2$O$_3$ = 9.6, in the clinoptilolite samples, to a degree of approximation one can apply the results obtained for silicon crystals$^{11}$, i.e. $\sigma_{Si} \approx 10^{-22}$ cm$^2$; $N_0 = 6 \times 10^{23}$ cm$^{-3}$. For the $\phi = 10^{13}$ e/cm$^2$ dose one can derive from (2):

$$N_{I,V} = 10^{-23} \text{ cm}^{-2} \cdot 6 \times 10^{23} \text{ cm}^{-3} \cdot 10^{13} \text{ cm}^{-2} = 6 \times 10^{13} \text{ e/cm}^2.$$  

These A-centers act as acceptors and are able to capture positively charged radionuclides in a practically useful amount from NPP waste waters.

The results presented herein are in accord with our previous findings for electro-physical and optical properties of zeolites, and in particular, an enhanced sorption of Cs$^+$ cations$^{2,6}$. 

---

**Figure 4** | Reduction of waste water radioactivity from ANPP depending on clinoptilolite sorbent electron irradiation processing degree.

**Figure 5** | Electron irradiation dose dependence of natural clinoptilolite dielectric constant $\varepsilon'$ for some frequencies of the electric field.

**Figure 6** | Electron irradiation dose dependence of the relative intensity of an absorption band at $\lambda = 1.91$ μm for the chemically treated and raw samples: 1 - treated by CH$_3$COOH; 2 - raw zeolite ( clinoptilolite); 3 - treated by NH$_4$Cl.
Both the fundamental scientific, and potential practical significance of these results makes it desirable to further the present studies and moreover to develop and design pilot industrial installations, taking into account factors such as: zeolite grain size, dimensions (diameter and length) of the column, water flow rate, optimum pH, to optimize the final cleaning technology for radioactive liquid waste and also municipal sewage processing.

Methods

Radiation-modified natural zeolites (mainly clinoptilolite) were tested for the treatment of water taken from the Armenian Nuclear Power Plant (ANPP). The radiation modification was performed by irradiating the zeolite samples at room temperature with 8 MeV electrons, and at various doses in the range 1·10^8 e/cm²–3·10^10 e/cm² with an error close to 15%, as produced by the linear electron accelerator ELU-8 at the Yerevan Physics Institute. By way of information, we note that for a zeolite, an irradiation dose of 10^8 e/cm² corresponds to an absorption dose in the range of 1 Mrad. All experiments were performed using untreated (raw) zeolite samples, i.e. as mined from the ground, which were then selected and granulated. An energy of 8 MeV was chosen according to previous experiments, in which we employed electrons with energies in the range 3 MeV–10 MeV, and discovered that 8 MeV electrons are optimal for the generation of point structural defects, while simultaneously avoiding disruption in the stoichiometry of the material, permitting a full penetration of electrons through the body of the sample and avoiding the induction of residual radioactivity. The clinoptilolite concentration in all the samples used was in the range 83–85%.

XRD analyses were applied to determine the clinoptilolite concentration in the samples, yielding crystallographic characteristics from which a pore size of 5·6–4·4 Å was defined. Samples containing up to 85% clinoptilolite, with the highest absorption capacity and a Si/Al ratio of 9·8, were selected from more than different 30 raw specimens. Other contaminations in the raw materials were determined, on the basis of chemical, I.R. and thermogravimetric analysis, to be: feldspar – 5%, quartz – 5%, mica – 2%, clays – 3%, with an error of 1%. A water absorption capacity of ca 20 wt% was obtained for a range of raw and chemically treated zeolite samples.

We have shown that the irradiation up to a dose of 3·10^10 electron/cm² significantly influences the properties of clinoptilolite. However, the corresponding changes in the dielectric and optical properties of these materials are non-monotonic which indicates the complexity of the underlying process (Fig. 5 and Fig. 6). The radioactivity and displacement effects on adsorbed water must also be considered. A radiation dose of 3·10^8 electron/cm² at an energy of 8 MeV appears critical to promote structural changes in these natural zeolite samples, which is signified by a pronounced variation in the dielectric properties and optical characteristics of the materials.

Most of the radioactivity in wastewaters from nuclear power plants is from Cs and Sr. How to cite this article: Yeritsyan, H. et al. Radiation-modified natural zeolites for cleaning liquid nuclear waste (irradiation against radioactivity). Sci. Rep. 3, 2900; DOI:10.1038/srep02900 (2013).
