A polynomial invariant of diffeomorphisms of 4–manifolds

DANIEL RUBERMAN

Abstract. We use a 1–parameter version of gauge theory to investigate the topology of the diffeomorphism group of 4–manifolds. A polynomial invariant, analogous to the Donaldson polynomial, is defined, and is used to show that the diffeomorphism group of certain simply-connected 4–manifolds has infinitely generated $\pi_0$.

AMS Classification 57R52; 57R57

Keywords Diffeomorphism, isotopy, 4–manifold

Dedicated to Rob Kirby on the occasion of his 60th birthday.

1 Introduction

The issue of whether topological and smooth isotopy coincide for diffeomorphisms of 4–manifolds was recently resolved in the author’s paper [16]. That work defined an invariant, roughly analogous to the degree–0 part of the Donaldson invariant of a 4–manifold, which serves as an effective obstruction to smooth isotopy. In the current paper, we will extend the definition of the invariant to give a polynomial-type invariant, which is analogous to the full Donaldson polynomial. As an application of the polynomial invariant, we will show that $\pi_0$ of the diffeomorphism group of certain 4–manifolds is infinitely generated.

It is worth stating this last result somewhat more precisely. For any compact 4–manifold $X$, one can consider its (orientation-preserving) diffeomorphism group $\text{Diff}^+(X)$. Taking the induced map on homology defines a homomorphism from $\text{Diff}^+(X)$ to the automorphism group of the intersection form of $X$; in many cases this map is a surjection. Let us denote by $\text{Diff}_H(X) \subset \text{Diff}^+(X)$ the kernel of this map.
Theorem A  Let $Z_n$ ($n \geq 2$) denote the connected sum
\[ \#_{k_n} \mathbb{CP}^2 \#_{l_n} \overline{\mathbb{CP}^2} \]
where $k_n = 2n$ and $l_n = 10n + 1$. Then there is a homomorphism
\[ D: \pi_0(\text{Diff}_H(Z_n)) \to \mathbb{R}[H_2(Z_n)^*] \]
with infinitely generated image.

The numbers appearing in the definition of $Z_n$ are less obscure than might appear at first glance; the manifold $Z_n$ is diffeomorphic to the elliptic surface $E(n)$, connected sum with $\mathbb{CP}^2$ and two copies of $\mathbb{CP}^2$. As will become evident in the proof, the conclusion that the image of $D$ is infinitely generated derives from the fact that $E(n)$ supports infinitely many smooth structures which become diffeomorphic upon connected-sum with $\mathbb{CP}^2$.

2  Invariants of diffeomorphisms

Let us start with a brief review of the definition of the 0–degree invariant discussed in [16]. The conditions discussed below having to do with orientations are used in defining the invariant as an element of $\mathbb{Z}$, rather than merely modulo 2. The data necessary for the definition are:

1. A smooth, simply-connected, oriented, homology-oriented 4–manifold $Y$ with $b_+^2 > 2$.
2. An SO(3) bundle $P \to Y$ such that $w_2(P) \neq 0$, and with $\text{dim}(\mathcal{M}(P)) = -1$. (Here $\mathcal{M}(P)$ is the moduli space of anti-self-dual connections on $P$.)
3. An integral lift $c \in H^2(Y; \mathbb{Z})$ of $w_2(P)$.
4. An orientation-preserving diffeomorphism $f$ of $Y$ such that $f^*(P) \cong P$, and such that the quantity $\alpha(f)\beta(f) = 1$.

The product $\alpha\beta \in \{\pm 1\}$ in the last item indicates, roughly, whether $f$ preserves or reverses the orientation of the moduli space. The numbers $\alpha$ and $\beta$ are themselves defined as follows:

• Composing a projection of $H^2(Y; \mathbb{R})$ onto $H^2_+(Y)$ with $f^*$ defines an isomorphism of $H^2_+(Y)$ with itself; the sign of the determinant (which is independent of all choices) determines the spinor norm, $\alpha(f) \in \{\pm 1\}$.
The condition that $f^* P \cong P$ implies that $f^* w_2 = w_2$, or in other words that $f^* c - c$ is divisible by 2 in $H^2(Y)$. One thereby can define $\beta(f) = (-1)^{(\frac{L(f) - \chi}{2})^2}$.

Under these conditions, for a generic metric $g \in \text{Met}(Y)$, the moduli space $\mathcal{M}(P; g_0)$ (connections which are $g_0$–anti-self-dual) is empty. If one considers instead a generic path $g_t \in \text{Met}(Y)$ of metrics from $g_0$ to $g_1 = f^* g_0$, then one can construct the 1–parameter moduli space

$$\tilde{\mathcal{M}}(P; \{g_t\}) = \bigcup_{t \in [0,1]} \mathcal{M}(P; g_t).$$

The count of points, with signs, in this 0–dimensional moduli space defines an invariant $D(f)$ (or $D_Y(f; P)$ if one needs to keep track of the manifold and/or the bundle).

The independence of $D(f)$ from the choice of initial metric $g_0 \in \text{Met}(Y)$ and of the choice of generic path are proved using a 2–parameter moduli space

$$\hat{\mathcal{M}} = \bigcup_{(s,t) \in I \times I} \mathcal{M}(P, K_{s,t}).$$

Here $K_{s,t}$ is a 2–parameter family of metrics giving a homotopy from one path of metrics $g_s = K_{s,0}$ to $k_s = K_{s,1}$. The proof in each case uses a choice of ‘boundary conditions’ for the endpoints of the homotopy. A fundamental point is that the parameter space $\text{Met}(Y)$ is simply connected, so that an arbitrary assignment of metrics on the boundary of the $(s, t)$ square $I \times I$ can be filled in smoothly. So for instance, to verify independence from the choice of path, use a 2–parameter family in which the endpoints are fixed: $K_{0,t} = g_0$ and $K_{1,t} = g_1$. To verify that the initial metrics $g_0$ and $k_0$ give the same value for $D(f)$, use an arbitrary path from $g_0$ to $k_0$ for $K_{0,t}$ with the proviso that the right endpoints $K_{1,t}$ are equal to $f^* K_{0,t}$.

In both arguments, the principle used is that on the one hand, the boundary of the 2–parameter moduli space $\hat{\mathcal{M}}$, which is a compact 1–manifold, consists of algebraically 0 points. On the other hand, the boundary is also the union of the 1–parameter moduli spaces associated to the four sides of the $(s, t)$ square. In the first case, the right and left sides of the square are fixed at generic metrics defining empty moduli spaces, so the boundary is the difference between the invariant computed with the two different paths on the top and bottom. In the second case, one must account for the additional part of the boundary, given by the difference between the (algebraic) count of points on the left and right sides. However, the choice of boundary conditions takes care of this, because
there is an isomorphism between $\tilde{M}(P; K_{0,t})$ and $\tilde{M}(P; f^*K_{0,t})$ and so the contributions from the two sides cancel.

### 2.1 A polynomial invariant of diffeomorphisms

It is natural to try to extend $D(f)$ to a polynomial in $H_0(Y) \oplus H_2(Y)$, by considering an SU(2) or SO(3) bundle $P$ for which the ASD moduli space $\mathcal{M}(P)$ has positive odd dimension, and cutting down by divisors. Recall that in the construction of the usual Donaldson polynomial, the divisor associated to a surface $\Sigma$ in $Y$ is defined in several steps. One first considers the space of irreducible connections on $\Sigma$, together with the restriction map $r_\Sigma: B^\ast(\Sigma) \rightarrow B^\ast(Y)$. Here $B^\ast(\Sigma)$ consists of connections whose restriction to $\Sigma$ is irreducible. An important remark (cf [5, section 9.2.3]) is that for a generic surface $\Sigma \subset Y$, the moduli space $\mathcal{M}(P)$ is contained in $B^\ast(\Sigma)$. There is a natural line bundle $L \rightarrow B^\ast(\Sigma)$, and one chooses a section, which is then pulled back to $B^\ast(Y)$. If these constructions are done with some care, then the zero-set of the pulled-back section defines a divisor $V_\Sigma$. Since we are only concerned with intersections of $V_\Sigma$ with $\mathcal{M}(P)$, we will follow the standard notational abuse and drop the superscript $\Sigma$. A similar construction gives a codimension–4 submanifold $V_x$ of $B^\ast(Y)$ which represents the dual of $\mu$ of a point $x \in Y$.

Now these constructions depend on a number of choices, e.g. the specific representative of the homology class $[\Sigma]$, and the choice of section of $L_\Sigma$. If the ‘space’ of possible choices were simply-connected, then one could incorporate them into the parameter space $\Pi$, and proceed precisely as in the definitions in Section 2 of [16]. The space of sections of $L_\Sigma$ is certainly contractible, and hence simply-connected. One can in fact make sense of the space of 2–cycles [1], and its fundamental group turns out to be precisely $H_3(Y)$. For our purposes, though, we do not need this remarkable fact, and will work directly with the condition that $H_3(Y) = 0$. By Poincaré duality, this is equivalent to assuming $H^1(Y) = 0$. For simplicity, we will in fact assume that $\pi_1(Y) = 0$. Thus $H_1(Y) = 0$, which in turn is the condition needed to incorporate the 0–dimensional class.

We will initially define a polynomial $D(f)$ of degree $d$, under one of two hypotheses. We assume that either $w_2(P) \neq 0$, or that invariants are being computed in the ‘strong’ stable range: $d \geq 2c_2(P) + 2$. Either of these assumptions will ensure, via the standard counting argument of Donaldson theory, the compactness of all of the low-dimensional moduli spaces which appear in the definition. In Section 3, we will prove a blow-up formula, which will then be used to define $D(f)$ in all degrees.
A polynomial invariant of diffeomorphisms of 4–manifolds

For a collection of homology classes $[\Sigma_i] \in H_2(Y)$, represented by embedded surfaces $\Sigma_i$, one could consider divisors $V_{\Sigma_i}$, in sufficient numbers so that the moduli space

$$\left( \bigcup_t \mathcal{M}(P; \{q_t\}) \right) \cap \left( \bigcap_i V_{\Sigma_i} \right)$$

is 0–dimensional. (The 0–dimensional class could be included, in a similar manner.) Let us write

$$D(P; \{q_t\}, V_{\Sigma_1}, \ldots, V_{\Sigma_d})$$

for the algebraic count of points in this intersection. $D(P; \{q_t\}, V_{\Sigma_1}, \ldots, V_{\Sigma_d})$ is readily seen to be independent of the choice path connecting $g_0$ and $f^*g_0$, by the same argument as outline above. However, the argument that this count is independent of representatives of the divisors and of initial metric $g_0$ breaks down. To see this (and what to do about it) consider, as in the discussion above two initial metrics $g_0 = K_{0,0}$ and $k_0 = K_{0,1}$, with a generic path $K_{0,t}$ between them. Following that construction, we take a 2–parameter family of metrics $K_{s,t}$ (with $K_{1,t} = f^*K_{0,t}$) and an associated 2–parameter moduli space $\tilde{\mathcal{M}}_{YM}$. Intersecting with the divisors $V_{\Sigma}$ gives a null-cobordism of $\partial\tilde{\mathcal{M}}_{YM}$. A priori, $f$ does not match up the right and left sides of this cobordism, as one would need in order to get a cobordism between top and bottom.

Indeed, $f$ induces an isomorphism between

$$\left( \bigcup_t \mathcal{M}(P; K_{0,t}) \right) \cap \left( \bigcap_i V_{\Sigma_i} \right) \quad \text{and} \quad \left( \bigcup_t \mathcal{M}(P; K_{1,t}) \right) \cap \left( \bigcap_i f^*V_{\Sigma_i} \right) \quad (1)$$

where $f^*V_{\Sigma}$ is the inverse image of $V_{\Sigma}$ under the diffeomorphism $f^*: \mathcal{B}(P) \to \mathcal{B}(P)$ induced by $f$. There is no good reason to expect that $f^*V_{\Sigma} = V_{\Sigma}$. Among other things, $f(\Sigma)$ might not even be homologous to $\Sigma$. In order to get a diffeomorphism invariant, some restrictions are needed; here is one approach.

Let $\mathcal{V}$ (or $\mathcal{V}(f)$ if the diffeomorphism needs to be specified) be the subgroup of $H_2(Y)$ fixed by the action of $f_*$; the invariant will be a polynomial in $H_0(Y) \oplus \mathcal{V}$. Represent an element in $\mathcal{V}$ by a generic surface $\Sigma$ in $Y$, and choose a generic 3–chain $C$ giving a homology between $\Sigma$ and $f(\Sigma)$. (From a technical point of view, it would perhaps be preferable to let $C$ be the image of an oriented 3–manifold via a smooth map to $Y$, but we will ignore this point for the moment.) As in Donaldson’s original work [4], consider a line bundle $\mathcal{L}_\Sigma \to \mathcal{B}^*(C)$ and a section $s_\Sigma$ whose pull-back to $\mathcal{B}(Y)$ defines the divisor $V_{\Sigma}$. Using the action of $f$, we get a section of $\mathcal{L}_{f(\Sigma)}$, whose divisor is $V_{f(\Sigma)}$. Now $\mathcal{L}_\Sigma$ and $\mathcal{L}_{f(\Sigma)}$ are

Geometry & Topology Monographs, Volume 2 (1999)
equivalent when pulled back to $B(C)$, and a choice of homotopy between their corresponding sections gives a cobordism $V_C$ between $V_\Sigma$ and $V_{f(\Sigma)}$.

By analogy with $D(P; \{g_t\}, V_{\Sigma_1}, \ldots, V_{\Sigma_d})$, we define, for any 3–chain $C_1$ and generic metric $g$, the invariant

$$D(P; g, V_{C_1}, V_{\Sigma_2}, \ldots, V_{\Sigma_d}) = \# \left[ \mathcal{M}(P; g) \cap (V_{C_1} \cap V_{\Sigma_2} \cdots \cap V_{\Sigma_d}) \right].$$

The term corresponding to the 3–chain can go in any slot, in place of the corresponding $V_{\Sigma}$.

Using the cobordisms $V_C$, we can finally give the actual definition of a polynomial invariant.

**Definition 2.1** Let $f: Y \to Y$ be an orientation preserving diffeomorphism. Assume that:

1. $H_1(Y) = 0$.
2. $P$ is an SO(3) or SU(2) bundle such that $f^*P \cong P$.
3. $w_2(P) \neq 0$ or (if $P$ is an SU(2) bundle) $d \geq 2c_2(P) + 2$.
4. $\alpha(f)\beta(f) = 1$.

Let $\Sigma_1, \ldots, \Sigma_d$ be generic surfaces carrying homology classes in $V = \ker(f_\ast - 1)$, and suppose that $-2p_1(P) - 3(b_2^+(Y) + 1) = 2d - 1$. Let $C_1, \ldots, C_d$ be generic 3–chains in $Y$ such that $\partial C_i = f(\Sigma_i) - \Sigma_i$. For a metric $g_0$ on $Y$, let $\{g_t\}$ be a smooth path such that $g_1 = f^*g_0$. Define

$$D_Y(f; \Sigma_1, \ldots, \Sigma_n) = D(P; \{g_t\}, V_{\Sigma_1}, \ldots, V_{\Sigma_d})$$

$$+ D(P; g_1, V_{C_1}, V_{\Sigma_2}, \ldots, V_{\Sigma_d})$$

$$+ D(P; g_1, V_{f(\Sigma_1)}, V_{C_2}, \ldots, V_{\Sigma_d})$$

$$\vdots$$

$$+ D(P; g_1, V_{f(\Sigma_1)}, V_{f(\Sigma_2)}, \ldots, V_{C_d}).$$

(2)

The term ‘generic’ for a metric $g$ means that the moduli space is smooth of the expected dimension, with no reducibles. All surfaces $\Sigma_i$ and 3–chains $C_j$, as well as sections of associated line bundles (and homotopies of such) are to be in general position, so the intersections with $\mathcal{M}(P; g)$ is smooth of the expected dimension as well. Without loss of generality, one can demand that the same is true of intersections with divisors $V_{f(\Sigma)}$ and $V_{f(C)}$ as well.
Remark This definition seems complicated, so some explanation may be helpful. The idea of the invariants under discussion is to use the moduli space associated to a path in the space of choices of parameters used in defining an ordinary invariant of a single 4–manifold. The parameter space involved in the usual degree–$d$ Donaldson invariant is roughly $\text{Met}(Y) \times (C_2)^d$ where $C_2$ is the space of 2–cycles in the relevant homology classes. The role of a path in the $k^{th}$ factor of $C_2$ is played by a 3–chain $C_k$. In these terms, the definition says to take a ‘path’ from $(g_0, \Sigma_1, \ldots, \Sigma_d)$ to $(f^*g_0, f(\Sigma_1), \ldots, f(\Sigma_d))$ which is a composition of paths, each having non-constant projection into one factor at a time.

Theorem 2.2 Under hypotheses (1)–(4) in Definition 2.1, $D_Y(f; \Sigma_1, \ldots, \Sigma_n)$ does not depend on the choice of initial generic metric $g_0$ and path $g_t$, on the choice of surfaces representing $[\Sigma_i]$, or on the choice of 3–chains $C_i$.

Proof The independence of $D(f)$ from choice (relative to the endpoints) of the path $g_t$ is identical to that given before, because the only term which could possibly change is the first. The independence from the initial point $g_0$ is more elaborate, as suggested by the discussion above. Let $k_0$ be another generic metric, and $K_{s,t}$ a 2–parameter family of metrics with

- $K_{0,t}$ a generic path from $g_0$ to $k_0$;
- $K_{s,0}$ a generic path from $g_0$ to $g_1 = f^*g_0$;
- $K_{s,1}$ a generic path from $k_0$ to $k_1 = f^*k_0$;
- $K_{1,t} = f^*K_{0,t}$.

As before, we get a 2–parameter moduli space

$$\tilde{\mathcal{M}}(P; \{K_{s,t}\}) = \left( \bigcup_{(s,t) \in I \times I} \mathcal{M}(P; K_{s,t}) \right) \cap (V_{\Sigma_1} \cap V_{\Sigma_2} \cdots \cap V_{\Sigma_d}) \quad (3.0)$$

which is a compact oriented 1–manifold.

Treating the 3–chains $C_j$ as parameters, in the spirit of the preceding remarks, we consider the following collection of 2–parameter moduli spaces, which again are 1–dimensional manifolds with boundary.

$$\tilde{\mathcal{M}}(P; \{K_{1,t}\}, C_1) = \tilde{\mathcal{M}}(P; \{K_{1,t}\}) \cap (V_{C_1} \cap V_{\Sigma_2} \cdots \cap V_{\Sigma_d}) \quad (3.1)$$
$$\tilde{\mathcal{M}}(P; \{K_{1,t}\}, C_2) = \tilde{\mathcal{M}}(P; \{K_{1,t}\}) \cap (V_{f(\Sigma_1)} \cap V_{C_2} \cdots \cap V_{\Sigma_d}) \quad (3.2)$$
$$\vdots$$
$$\vdots$$
$$\tilde{\mathcal{M}}(P; \{K_{1,t}\}, C_d) = \tilde{\mathcal{M}}(P; \{K_{1,t}\}) \cap (V_{f(\Sigma_1)} \cap V_{f(\Sigma_2)} \cdots \cap V_{C_d}) \quad (3.d)$$
The boundary of each of the 1–dimensional moduli spaces (3.0), (3.1), . . . , (3.d) has algebraically 0 points. As discussed before, the boundary of each 2–parameter moduli space can alternatively be described as the sum of the algebraic counts of points in appropriate 1–parameter moduli spaces. This leads to $d + 1$ equations:

$$0 = D(P; \{k_s\}, V_{\Sigma_1}, \ldots, V_{\Sigma_d}) - D(P; \{g_s\}, V_{\Sigma_1}, \ldots, V_{\Sigma_d})$$

(4.0)

$$- D(P; \{K_{0,t}\}, V_{\Sigma_1}, \ldots, V_{\Sigma_d}) + D(P; \{K_{1,t}\}, V_{\Sigma_1}, \ldots, V_{\Sigma_d})$$

$$0 = D(P; k_1, V_{C_1}, V_{\Sigma_2}, \ldots, V_{\Sigma_d}) - D(P; g_1, V_{C_1}, V_{\Sigma_2}, \ldots, V_{\Sigma_d})$$

(4.1)

$$- D(P; \{K_{1,t}\}, V_{\Sigma_1}, V_{\Sigma_2}, \ldots, V_{\Sigma_d}) + D(P; \{K_{1,t}\}, V_{f(\Sigma_1)}, V_{\Sigma_2}, \ldots, V_{\Sigma_d})$$

\vdots

$$0 = D(P; k_1, V_{f(\Sigma_1)}, V_{f(\Sigma_2)}, \ldots, V_{C_d}) - D(P; g_1, V_{f(\Sigma_1)}, V_{f(\Sigma_2)}, \ldots, V_{C_d})$$

(4.d)

$$- D(P; \{K_{1,t}\}, V_{f(\Sigma_1)}, V_{f(\Sigma_2)}, \ldots, V_{\Sigma_d}) + D(P; \{K_{1,t}\}, V_{f(\Sigma_1)}, V_{f(\Sigma_2)}, \ldots, V_{f(\Sigma_d)})$$

Adding these equations together, most of the terms cancel in pairs, leaving the difference between the invariant calculated with the paths $\{k_s\}$ and $\{g_s\}$, plus

$$D(P; \{K_{1,t}\}, V_{f(\Sigma_1)}, V_{f(\Sigma_2)}, \ldots, V_{f(\Sigma_d)}) - D(P; \{K_{0,t}\}, V_{\Sigma_1}, \ldots, V_{\Sigma_d}).$$

However, the isomorphism (1), coupled with the orientation hypothesis that $\alpha(f)\beta(f) = 1$, means that the two terms are equal, and so the invariant doesn’t depend on the choice of initial metric $g_0$.

The other choices of parameters involved in the definition of $D(f)$ are: the specific surface representing $[\Sigma_i]$, the choice of section defining $V_{\Sigma_i}$, the choice of 3–chain $C_i$ with $\partial C_i = f(\Sigma_i) - \Sigma_i$, and the section defining $V_{C_i}$. As remarked earlier, the verification that, for fixed $\Sigma_i$, the choices of section don’t affect the value of $D(f)$ is virtually identical to arguments given above, because sections vary in a contractible space. A similar remark applies to the choice of $V_C$, given a specific 3–chain $C$.

The independence from the choice of $\Sigma$’s and $C$’s differs in that a substitute must be found for one basic mechanism: the existence of the family $K_{s,t}$ derives from the fact that the space of metrics is simply connected. The idea is the same for all of the choices; we will illustrate the point in the simplest instance. So suppose that two 3–chains $C_1$ and $C'_1$ are given, both of which have boundary $f(\Sigma_1) - \Sigma_1$. The only place in equation (2) in which $C_1$ enters is in the term

$$D(P; g_1, V_{C_1}, V_{\Sigma_2}, \ldots, V_{\Sigma_d}).$$

Because the 3–chains have the same boundary, it follows that $C'_1 - C_1$ is a 3–cycle which is a boundary of a 4–chain $\Delta$, by our hypothesis that $H_3(Y) = 0$. 

*Geometry & Topology Monographs, Volume 2 (1999)*
One can use restriction to connections on $\Delta$ to define a 1–dimensional moduli space $\mathcal{M}$. Taking the boundary of this moduli space gives

$$D(P; g_1, V_{C_1}, V_{\Sigma_2}, \ldots, V_{\Sigma_d}) = D(P; g_1', V_{C_1'}, V_{\Sigma_2}, \ldots, V_{\Sigma_d})$$

by the standard argument.

A similar technique may be used to incorporate the 0–dimensional class. The invariant is readily checked to be multilinear, and so defines a polynomial invariant in $P[H_0(Y) \oplus \mathcal{V}(f)]$. Some other basic properties are summarized in the following theorem; they are analogous to properties which hold for the degree 0 part, and are proved in the same way.

**Theorem 2.3** Let $f$ and $g$ be diffeomorphisms for which invariants $D_Y(f)$ and $D_Y(g)$ are defined.

1. The polynomials of a composition are defined on $H_0(Y) \oplus \mathcal{V}(f, g)$, where $\mathcal{V}(f, g) = \mathcal{V}(f) \cap \mathcal{V}(g)$, and satisfy

   $$D_Y(f \circ g) = D_Y(g \circ f) = D_Y(f) + D_Y(g).$$

2. The polynomial of $f^{-1}$ is $-D_Y(f)$.

3. If $f$ and $g$ are isotopic, then $D(f) = D(g)$.

Because the applications are all to simply-connected manifolds, we haven’t stated the theorems in maximum generality. The weakest set of hypotheses which would give rise to an invariant of the type described in this section would seem to be that $H_1(Y; \mathbb{Q}) = 0$, and that $w_2(P)$ is not the pullback of a class in $H^2(B\pi_1(Y); \mathbb{Z}_2)$. The invariant would then be $\mathbb{Q}$ rather than in $\mathbb{Z}$–valued.

### 3 Some basic theorems of 1–parameter gauge theory

In this section we will state (and sketch proofs of) analogues of the basic connected-sum and blowup formulas for the Donaldson invariant. Undoubtedly, more elaborate versions of the gluing principles in gauge theory will work in the 1–parameter context, but we will state only those theorems which we actually use. The simple situation in which we work may be summarized in the following definition.

*Geometry & Topology Monographs, Volume 2 (1999)*
Definition 3.1 Suppose that $f$ and $g$ are diffeomorphisms of manifolds $X$ and $Y$, which are the identity near base points $x$ and $y$. The connected sum $f \# g$ is the obvious diffeomorphism on the connected sum $X \# Y$; it depends up to isotopy only on the isotopy classes of $f$ and $g$ relative to neighborhoods of the base points.

A useful (cf [13]) technical device for the ordinary Donaldson polynomial is the fact that no (rational) information is lost if one replaces a manifold by its connected sum with $\mathbb{C}P^2$. A similar principle holds for the 1–parameter invariants. To state this, let $L_0 \to \mathbb{C}P^2$ be the complex line bundle such that $c_1(L_0)$ is Poincaré dual to the exceptional curve $E$ in $\mathbb{C}P^2$.

Theorem 3.2 Suppose that the polynomial invariant $D(f, P)$ is defined for a diffeomorphism $f: Y \to Y$. Then the invariant $D(f \# id_{\mathbb{C}P^2}, P \# (L_0 \oplus \mathbb{R}))$ is defined, and satisfies

$$D(f \# id_{\mathbb{C}P^2}, P \# (L_0 \oplus \mathbb{R}))(E, E) = -2D(f, P).$$

Proof Choose a path of metrics and a collection of 3–chains $C_i$ with $\partial C_i = f(\Sigma_i) - \Sigma_i$ which define $D(f, P)$. The path can assumed to be constant near the connected sum point, so it extends to give a path of metrics on $Y \# \mathbb{C}P^2$.

Similarly, the 3–chains can be assumed to miss the connected sum point, so they are 3–chains in the connected sum in a natural way.

Now we use a standard gluing argument: choose a metric on $Y \# \mathbb{C}P^2$ with a long tube along the $S^3$. For sufficiently long tube length, we can calculate each term in the definition of the invariant. The 3–chain $C$ with $\partial C = f(C) - C$ may be taken to be degenerate, so that the last two terms (of the form $D(P; g_1, V_{f(\Sigma_1)}, V_{f(\Sigma_2)}, \ldots, V_{f(\Sigma_d)}, V_{f(E)}, V_C)$) are 0 for dimensional reasons. The moduli spaces corresponding to the other terms in the definition, may all be described by the Kuranishi model for the 1–parameter moduli space, as in [16]. The local picture, and hence the calculation of the coefficients, is the same as in the proof of the usual blowup formula.

Following the scheme laid out in [13], we can extend the definition of the invariants $D(f)$ outside the ‘stable range’ by repeatedly blowing up to increase the energy, and then using (5). The result is that the invariant of $f$ is a collection of rational-valued polynomials of arbitrary degree in $H_0(Y) \oplus V(f)$. Following [9] we introduce the notion of a diffeomorphism being of simple type, and assemble the polynomials into a formal power series $D(f)$, which we will call
A polynomial invariant of diffeomorphisms of 4–manifolds

the Donaldson series of $f$. In the examples discussed below and in the next
section, the power series are determined by a set of basic classes, as in the main
theorem of [9]. It would be of interest to know if such a structure theorem holds
more generally under the simple type hypothesis.

There is also a version of the connected sum theorem; the proof is a simple
dimension-counting argument and will be omitted.

Theorem 3.3 Suppose that $f_i : Y_i \to Y_i$ are diffeomorphisms, where $Y_i$
(for $i = 1, 2$) are 4–manifolds satisfying $b_2^+(Y_i) \geq 2$. Then any invariant
$D(f_1 \# f_2, P_1 \# P_2)$ which is defined must vanish.

The remaining case to investigate is when $b_2^+(Y_1) \geq 2$ and $b_2^+(Y_2) = 1$. The
result is more complicated, and it depends on the behavior of the diffeomor-
phism $f_2$. The basic idea is that the evaluation of the 1–parameter invariant
on homology classes supported in $Y_1$ is, in some circumstances, the product
of an ordinary Donaldson invariant of $Y_1$ with a term related to the wall-crossing
phenomenon characteristic of gauge theory on manifolds with $b_2^+ = 1$. A com-
pletely general treatment would run into unresolved problems associated with
that theory (under the general rubric of the Kotschick–Morgan conjecture—
cf [7, 8]). We will state a relatively simple version, which avoids these techni-
calities, but which suffices for the main application. A reasonable extension of
this statement, parallel to the Kotschick–Morgan conjecture, would be that the
restriction of $D(f_1 \# f_2)$ to $H_2(Y_1)$ depends in some universal fashion on $D(f_1)$
and the action of $f_2$ on cohomology. The full polynomial (ie including $H_2(Y_2)$)
is also of interest.

Let $N$ be a simply-connected manifold with $b_2^+ = 1$, and let $L \to N$ be a
complex line bundle with $c_1(L)^2 = -1$. Note that this implies that $w_2(P_N) \neq 0$,
where $P_N$ is the SO(3) bundle over $N$ associated to $L \oplus \mathbb{R}$. A choice of
orientation for $H_2^+(N)$ picks out a positive sheet of the hyperboloid $\mathcal{H} = \{ \alpha \in
H_2^+(N) | \alpha^2 = 1 \}$. Inside $\mathcal{H}$ lie the walls $\mathcal{W}$, where a wall is the orthogonal
complement (intersected with $\mathcal{H}$) of a class $x \in H^2(N; \mathbb{Z})$ satisfying $x \equiv c_1(L)$
(mod 2) and $x^2 = 1$. The walls are transversally oriented, and form a locally
finite something or other. Note that any metric $g$ on $N$ determines a unique
self-dual harmonic form $\omega_g \in \mathcal{H}$, called its period point.

Let $f_N$ be a diffeomorphism of $N$ which is the identity near a point of $N$, which
has the property that $f_N^* \omega_g$ preserves $w_2(P_N)$, and satisfies $\alpha(f_N)^\beta(f_N) = 1$.
Such diffeomorphisms were constructed on $N = \mathbb{CP}^2 \# 2 \mathbb{CP}^2$ in section 3 of [16],
and easily extend to arbitrary connected sums $\mathbb{CP}^2 \# k \mathbb{CP}^2$. Let $g_0^N$ be a metric
on \( N \), which is fixed by \( f \) near the connected sum point, and whose period point does not lie on any of the walls. Join \( g_0^N \) to \( f^*(g_0^N) \) by a path whose induced path \( \gamma \) of period points is transverse to \( W \). Using the transverse orientation of \( W \), the intersection number of this path with \( W \) is well-defined.

**Theorem 3.4** Let \( f \) be the diffeomorphism of \( Z = Y \# N \) gotten by gluing \( f_N \) to the identity of \( Y \). Then \( D_Z(f) = 2(\gamma \cdot W)D_Y \).

4 Applications to the topology of the diffeomorphism group

The 1–parameter invariants, as extended in the previous section, fit together naturally to give a homomorphism which will show that \( \pi_0(\text{Diff}_H) \) can be infinitely generated, proving Theorem A of the introduction. (Recall that \( \text{Diff}_H(Z) \) is the subgroup of the diffeomorphism group consisting of diffeomorphisms which act trivially on homology.)

There is a small technical observation to be made in order to draw conclusions about \( \pi_0(\text{Diff}) \) from our results. Namely, two diffeomorphisms are in the same path component of \( \text{Diff} \) if and only if they are isotopic. This seems a little surprising at first, because there is no smoothness required for a path in \( \text{Diff} \).

The proof relies on simple properties of the Whitney \( C^\infty \) topology on smooth maps, and is quite standard in the subject—compare [14, Definition 3.9 and Problem 4.6] and [2].

Combining this observation, the definition of the Donaldson series of a diffeomorphism, and Theorem 2.3, we get the following result.

**Theorem 4.1** Let \( Y \) be a 4–manifold with \( b^2_+ \) an even number \( \geq 4 \). Then the Donaldson series defines a homomorphism

\[
D: \pi_0(\text{Diff}_H(Y)) \to \mathbb{R}[[H_2(Y)^*]].
\]

The proof of Theorem A will be completed by showing that for the manifolds \( Z_n \) described in the introduction, the image is infinitely generated.

**Proof of Theorem A** Suppose that \( Z \) is of the form \( Y \# N \), where \( N = \mathbb{C}P^2 \#_2 \mathbb{C}P^2 \), and notice that restriction defines a homomorphism

\[
r^*_Y: \mathbb{R}[[H_2(Z)^*]] \to \mathbb{R}[[H_2(Y)^*]].
\]
Let $f$ be a diffeomorphism of the form $id_Z \# f_N$, as discussed before Theorem 3.4. In particular, $f_N$ should be chosen as a composition of reflections in two different $(-1)$–spheres, as in [16]; the intersection number $\gamma \cdot W$ is computed in that paper to be $-2$. Suppose finally that $Y$ has simple type in the sense of [9], so that its Donaldson series $D_Y$ is determined by a finite set of basic classes $\kappa_i(Y) \in H^2(Y; \mathbb{Z})$. Rewriting Theorem 3.4 in terms of the Donaldson series of $f$, we see that $r^*_Y D(f) = -4D_Y$. In particular, $r^*_Y D(f)$ has the form described by the structure theorem of [9], and so is determined by the same set of basic classes $\kappa_i(f) = \kappa_i(Y)$. Moreover, the coefficients $\beta_i(f)$ in the expression of the series as a sum of exponentials of the $\kappa_i$, are equal to the corresponding coefficients for $Y$.

Under composition of diffeomorphisms the Donaldson series add. For diffeomorphisms $f, g \in \text{Diff}_H(Z)$ whose series are determined by basic classes, this implies the following statement. The set of basic classes for $f \circ g$ is the union of the set of basic classes for $f$ and for $g$, leaving out those basic classes which $f$ and $g$ have in common but whose coefficients cancel. In other words, a basic class $\kappa_i(f) = \kappa_j(g)$ is removed from the union if the coefficient $\beta_i(f) = -\beta_j(g)$.

In the paragraphs which follow, we will show that if $Z$ is any one of the manifolds described in the statement of Theorem A, then it admits a series of diffeomorphisms $\{f_j\} (j = 1, \ldots, \infty)$ which are all homotopic to the identity, with the property that $f_m$ has at least $m$ different basic classes. We claim that the image under $D$ of the subgroup of $\pi_0(\text{Diff}_H(Z))$ generated by the $f_j$ is infinitely generated. Suppose that the diffeomorphisms have been indexed so that $f_m$ has at least one basic class which does not occur in the list of basic classes for $f_j$ for $j < m$. Note that if $K_1, \ldots, K_n$ are distinct elements in $H^2(Y)$, then the exponentials $\exp(K_1), \ldots, \exp(K_n)$ are linearly independent elements in the power series ring $\mathbb{R}[[H^2(Y)^*]]$. Thus in any any linear relation

$$\sum_{j=1}^m a_j D(f_j) = 0$$

the coefficient $a_m$ must be 0. The claim follows immediately by induction, and so we have that $\pi_0(\text{Diff}_H(Z))$ is infinitely generated.

Let $Y_n$ denote $\#_{2n-1} \mathbb{CP}^2 \#_{10n-1} \overline{\mathbb{CP}}^2$ for $n$ odd, and $\#_{2n-1} \mathbb{CP}^2 \#_{10n} \overline{\mathbb{CP}}^2$ for $n$ even. The manifold $Z_n$ will be simply $Y_n \# N$, where $N = \mathbb{CP}^2 \#_2 \overline{\mathbb{CP}}^2$ as before. Let $E(n)$ be the simply-connected elliptic surface with $p_g = n - 1$ and no multiple fiber, and let $E(n;p)$ denote the result of a single logarithmic transform on a fiber in $E(n)$. The standard convention is that $E(n;1)$ is the same as $E(n)$.
We will make use of the following facts about these manifolds.

1. For $n$ odd, $E(n; p) \simeq Y_n$, and for $n$ even, $E(n; p) \# \mathbf{CP}^2 \simeq Y_n$.
2. $E(n; p) \# \mathbf{CP}^2$ decomposes completely into a connected sum of $\mathbf{CP}^2$’s and $\overline{\mathbf{CP}}^2$’s. See [11] or [10, 12] for more details.
3. The diffeomorphism group of $Y_n \# \mathbf{CP}^2$ acts transitively on elements in $H_2(\mathbb{Z}_n)$ of given square, divisibility, and type (i.e. characteristic or not) [17].
4. The Donaldson series for $E(n; p)$ is given [6] by
   \[
   D_{E(n; p)} = \exp \left( \frac{Q}{2} \right) \frac{\sinh^{n-1}(f)}{\sinh(f_p)}
   \]
   where $f_p$ is the multiple fiber (and therefore the regular fiber $f = pf_p$ in homology).
5. The Donaldson series for $E(n; p) \# \mathbf{CP}^2$ is
   \[
   D_{E(n; p) \# \mathbf{CP}^2} = D_{E(n; p)} e^{-E^2} \cosh(E)
   \]
   where $E$ is dual to the exceptional class.

The argument differs in minor details between the cases when $n$ is even or odd; for simplicity we will concentrate on $n$ odd. The main point of this is that $E(n; p)$ is not spin when $n$ is odd.

Let $S_0$ denote the standard (complex) 2–sphere in $\mathbf{CP}^2$, viewed as a submanifold in $Y_n \# \mathbf{CP}^2$, and let $S'_p$ denote the analogous sphere in $E(n; p) \# \mathbf{CP}^2$. Using the first two items, choose a diffeomorphism of $E(n; p) \# \mathbf{CP}^2$ with $Y_n \# \mathbf{CP}^2$.

Since $S'_p$ is not characteristic, any initial choice of diffeomorphism may be varied by a self-diffeomorphism of $Y_n \# \mathbf{CP}^2$ to ensure that the image of $S'_p$ is homologous to $S_0$. Denote this image, viewed as a sphere in $Y_n \# \mathbf{CP}^2$ or in $\mathbb{Z}_n$, by $S_p$. Note that the homology of $Y_n$ may be identified with the orthogonal complement to $S_p$, with respect to the intersection pairing, and hence the image of $H_2(E(n; p))$ is $H_2(Y_n)$.

As in [16], the $(-1)$–spheres $S_p \pm E_1 + E_2$ in $\mathbb{Z}_n$ give rise to reflections $\rho^\pm_p$, and we set
\[
   f_p = (\rho^+_p \circ \rho^-_p) \circ (\rho^+_0 \circ \rho^-_0)^{-1}.
\]
Because $S_p$ and $S_0$ are homologous, the action of $f_p$ on homology is trivial, and thus [15, 3] $f_p$ is homotopic to the identity. The image of $D(f_p)$ under $r_\delta^*$ is the Donaldson series of $E(n; p)$, and so is given by the formula in item 4 above. Expanding the hyperbolic sines, we see that $E(n; p)$ has $(n-1)$ basic classes, and so there are the same number of basic classes for $r_\delta^*(D(f_p))$. Thus the $f_p$ generate an infinitely generated subgroup of $\text{Diff}_H(\mathbb{Z}_n)$.
