1. Introduction

Exploration of novel materials and improved micro- and nano-fabrication techniques are bringing up a new class of brain–computer interfaces (BMIs) which promise to revolutionize neuroprosthetics and unveil the underlying vast functionalities of the brain. Impressive breakthroughs have been recently achieved in motor control rehabilitation, understanding the mechanisms for learning and formation of memory, treating neuropsychiatric disorders (e.g. depression) and synthesizing audible speech using machine learning algorithms, emphasizing the immense potential BMIs have [1–10]. While the presented capabilities to interface with the brain are already very impressive, they mostly rely on relatively simple epicortical electrode arrays with low number of recording sites and large inter-site spacing, and are unsuitable for long chronic implantation. Higher cognitive functions do typically arise from a complex interplay of activity in several brain regions at once, therefore a detailed analysis of the neural activity underlying such functions would require sensor arrays recording from all involved areas with high local resolution in each of them. Current commercially available neural sensor arrays fail to provide the high sensor counts necessary for such endeavor, mostly due to the technologic challenge of excessive wiring with increasing array size, which could only be overcome by the employment of multiplexed...
read-out circuitry. Multiplexing strategies are not new to the field of neuro-sensing and have previously been used as a versatile tool to manage large amounts of recording sites. Most of the emerged technologies are based on a CMOS–compatible monolithic integration of recording electrodes and read-out electronics to minimize connection distance for preserving signal integrity and maximizing the density of recording sites. Using rigid silicon substrates, however, restricts such concepts to applications in which device flexibility is expendable such as depth-probes or MEAs for ex–vivo recordings [11–14]. Yet, considering the extensive damage rigid depth-probes cause to the brain tissue, sets a clear limitation to the amount of insertable shanks and thus the simultaneously mappable brain regions. Here, electrocorticography offers a minimally invasive alternative with clear advantage on sensor resolution over large areas by using flexible μECoG arrays to record from the surface of the cortex [15]. Still, so far only very few examples of multiplexed μECoG arrays have been realized, due to the scarcity of durable materials for low-noise, high-performance switches compatible with flexible substrates as well as the high level of complexity such device fabrication requires. An example is the work of Rodgers which utilizes a combination of buffer and addressing transistor (ultrathin Si) to process the signals of an array of 360 passive platinum electrodes [16, 17]. Using passive elements, i.e. electrodes, as sensors requires the implementation of an additional transducer (buffer transistor) to decouple the electrode from the read-out circuitry, which otherwise would lead to load currents affecting the electrodes performance. This additional complexity can be avoided by directly using active elements i.e. transistors to interface with the brain. Such approach has recently been explored for organic electrochemical transistors (OECTs) with the conductive polymer poly(3, 4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT: PSS) as channel material [18–20].

As the brain consists of corrugated soft tissue moving at every heartbeat, highly flexible probes are imperative to create intimate interfaces for best signal quality and to avoid gradual cicatrizing of the neural tissue. In this work, we present flexible multiplexed μECoG arrays based on active sensing devices, namely graphene solution-gated field-effect transistors (gSGFETs). The gSGFET has emerged as one of the most promising technologies for brain–machine interfaces (BMIs) as it provides essential properties such as biocompatibility, chemical stability, mechanical flexibility and high signal-to-noise ratio [21, 22]. In particular, it has shown great potential for application in μECoG arrays with its high sensitivity over a broad frequency range (0.001 Hz up to 10 kHz), making it an efficient transducer of both infra-slow and fast neural activity [21, 23]. While the gSGFETs suitability to provide high-quality recordings has already been proven for up to 16 recording sites in previous publications, its potential has never been evaluated for high-density arrays of large sensor count. Graphene is commonly considering as an ideal material for high-frequency application, which makes it an interesting candidate to consider for multiplexed devices. With typical mobilities around 1000–2000 cm² V⁻¹ s⁻¹ for CVD grown graphene, it can easily surpass organic electronic materials such as PEDOT:PSS and reaches similar values as in silicon, with respective mobilities of 0.01 cm² V⁻¹ s⁻¹ and 1400 cm² V⁻¹ s⁻¹. However, considering the current technology development, it is reasonable to expect further improvement and experimental values as high as 350 000 cm² V⁻¹ s⁻¹ have already been reported under ideal conditions [24, 25]. Moreover, we demonstrate that by using active sensing devices, the integration of multiplexing circuitry, i.e. buffer and switching transistors, is unnecessary, thus drastically easing the complexity of fabricating flexible multiplexed sensor arrays.

2. Methods

2.1. Probe fabrication

In a first step 10 μm thick biocompatible Polyimide (PI-2611 HD MicroSystems) was spun on 4 Si/SiO₂ support wafers and cured under nitrogen atmosphere at 350 °C. The perpendicular metal lines of the array (columns/rows) were patterned in two standard lift-off steps (negative photoresist AZ5214E, Clariant, Germany) with the metal deposited by e-beam evaporation (30 nm Ti/300 nm Au, 10 nm Ti/100 nm Au) and separated by a 2 μm PI spacer layer. Interconnecting via-holes through the spacer layer were etched by oxygen plasma using a photolithographically defined protective aluminum mask (AZ5214E, 300 nm Al). Then, single layer graphene, grown and transferred by Graphenea, is patterned by photolithography (H6512 photoresist) and etched by oxygen-based reactive ion etching (100 W for 1 min) to form the transistor channel area. A third metal layer (20 nm Ni/200 nm Au) is added to form sandwich contacts improving the gSGFET’s durability and lowering its contact resistance due to work function matching. A subsequent thermal annealing step at 300 °C in ultra-high vacuum has been found to reduce surface contamination from photoresist residues and improving the conformity of the Ni–graphene interface, thus improving contact resistance and device performance. To passivate the metal leads, a 2 μm thick layer of SU8 epoxy photoresist (SU-8 2005 MicroChem) was deposited, leaving open windows in the channel regions to allow a direct electrolyte graphene interface. In a final step, the polyimide was structured by deep reactive ion etching using a photoresist etching mask (AZ9260, Clariant) and the flexible probes were mechanical peeled from the support wafer.
2.2. Characterization and multiplexing setup

Custom-build electronics were used for bias control and to convert the drain source current signal into voltage by a transimpedance amplifier (10 kΩ gain). The voltage signal was split into DC (frequency < 0.1 Hz) and AC (0.1 Hz < frequency > 5 kHz) components. The AC signal is amplified by an additional factor of 100 for the noise evaluation. The voltage read out was done by a standard data acquisition system (National Instruments DAQ-Card, USB-6363). For the multiplexed data acquisition, a similar system was used as for the probe characterization, however the gain of the AC stage was reduced by a factor of 10 to prevent saturation of the amplifier’s dynamic range due to mismatch in transistor resistance. The digital output lines were used to address the n-type MOSFET switching matrix by applying either +5 V for ON- and 0 V for OFF-state. All software to control the DAQ-Card and handle data acquisition is based on self-built python code.

2.3. In-vivo experiments

Long Evans rats (Charles River) were kept under standard conditions (room temperature 22 ± 2 °C, 12:12 h light–dark cycle, lights on at 10:00). Food and water were provided ad libitum. All experiments were performed in accordance with the European Union Directive 2010/63/EU as well as the German Law for Protection of Animals (TierSchG) and approved by the local authorities (ROB-55.2-2532.Vet_02-16-170). Three adult rats (2 males, 1 female), 3–8 month of age, weighing in the range of 400–600 g were used in this study. In preparation of electrophysiological measurements, they were deeply anaesthetized with MMF (Midazolam 2 mg/kg), Medetomidin 0.15 mg kg⁻¹, Fentanyl 0.005 mg kg⁻¹ and supplemented after 1 h with Isoflurane 0.5%–1% and Metamizol at 110 mg kg⁻¹. After subcutaneous infiltration with Bupivicain the skin above the cranium was incised and the dorsal skull surface exposed. Craniotomies were performed bilaterally, with a maximum width of 5 mm and extending anterior-posteriorly between +2 mm and −8 mm with respect to bregma. The dura mater was opened and carefully resected. The craniotomies were flapped open partially and the gSGFET array was placed on the right hemisphere while the NeuroNexus array (E32-600-10-100) was symmetrically positioned on the left hemisphere, (between ca −7 and −3 mm from bregma) each partially covering the primary visual cortex. Subsequently the PDMS covers were flapped back to cover arrays and craniotomies. A reference wire (Ag/Ag-Cl) was inserted either in the cerebellar craniotomy (n=1) or temporal muscle (n=2). Data from the NeuroNexus array was acquired at 25 kHz using the eCube recording system (WhiteMatter LLC) while data from the gSGFET was acquired using custom build electronics described in the previous section. Anesthesia was kept at 0.5% iso-flurane during the recordings of spontaneous activity and cortical spreading depression (CSD) and 2% isoflurane for the recording of optically evoked activity with reduced spontaneous activity. The CSD event was triggered by application of 1µL KCl (3 mMol) with a glass–micropipette and Nanoeject II injection device (Drummond Scientific) at ca 4 mm anterior to bregma, approximately 7 mm anterior to the closest site on the recording array. The optically evoked response was triggered by a contralaterally placed blue LED (PlexonBright LED, 465 nm wavelength, 5 mW power output at fiber end) in front of the left eye in around 5 cm distance, which delivered 100 msec light pulses every 5 s.

3. Results and discussion

3.1. Device performance and multiplexing methodology

Scalable thin-film technology of 8 × 8 gSGFET sensor arrays was fabricated on 7 µm thick flexible polyimide (PI) using 4 inch support wafers. The layout of the probe can be seen in figure 1(a) and consists of a stack of two metal layers constructing the perpendicular lines of the sensor grid with a separating PI layer in between. The 64 gSGFET sensors have single-layer graphene channels of 50 µm × 50 µm dimension and 400 µm inter-site separation (detailed description of probe fabrication in experimental section). The quality of the transferred graphene films was characterized by Raman spectroscopy (two maps of each 10 µm × 10 µm), showing a mean full-width half-maximum of the 2D-peak of 39.92 cm⁻¹ and a mean I_{2D}/I_G-ratio of 2, characteristic for the predominant presence of monolayer graphene. The amount of second nucleation and the defect density were found to be low, with around 3% multilayer area and a mean I_{2D}/I_G-ratio of 0.05 (see Supplementary information (stacks.iop.org/2DM/7/025046/mmedia)). A picture of the final probe, after releasing it from the Si support wafer is shown in figure 1(c). In contrast to their solid-state counterparts, solution-gated transistors are being modulated through the creation of a charge double layer at the interface between transistor channel and an electrolyte solution.

Potential fluctuations in the surroundings (e.g. neural activity) can modulate this double layer and result, in turn, in a shift of the Fermi level of the channel material, which is detectable as a current fluctuation. Graphene’s ability to create a stable interface with aqueous solutions in combination with its high transconductance, resulting from its large interfacial capacitance and carrier mobility,
Figure 1. Multiplexed gSGFET µECoG-array: (a) Layout and cross section of flexible ECoG array with 64 gSGFETs showing the grid construction with two metal layer and tapered via-holes (Figure S1 is available online at stacks.iop.org/J/V/A/mmedia in supporting information) crossing the PI interlayer. (b) gSGFET's transfer curve showing the change of drain-source current with applied gate bias ($I_{ds}-U_{gs}$, measured at $U_{ds}=100$ mV), its transconductance ($G_m-U_{gs}$) and the device's equivalent gate noise ($U_{rms}-V_{gs}$). Also, the respective distribution of each parameter at peak $G_m$ (bias point yielding highest absolute transconductance) across the array is being shown in the adjacent color map. (c) Picture of flexible probe after release from Si support wafer. (d) Schematic of discrete multiplexing setup using a DAQ-card for bias control and read-out (blue) and a custom-build PCB board for switching (yellow), filtering and current-to-voltage conversion (red). (e) Acquired DC and AC raw signal for one column showing eight distinct current levels corresponding to the transistors in each row, which repeat for every cycle (grey dashed line). Due to the high gain (100 k) applied to the AC component of the signal, the dynamic amplifier range sets a limit to the allowable current mismatch between devices, before amplifier saturation occurs (solid red line). (f) From the 10 data points taken for each transistor per cycle, an average value of the last 5 points is taken, to yield one sample in the final reconstructed signal for each sensor.
makes the gSGFET an ideal device for bio-sensing [21–23, 26–29]. Figure 1(b) shows a performance and homogeneity assessment of the gSGFET array. The transfer curve, namely the change of drain-source current $I_{ds}$ with applied gate bias $U_{gs}$ is presented as an averaged value and for all 64 individual devices, with the boxplot indicating the variation of charge neutrality point (CNP). Extracting the field-effect mobility in the linear regime of the transfer curve ($U_{gs} = 0.2 \, V$) results in a mean value of 1827 cm$^2$ V$^{-1}$ s$^{-1}$ with a standard deviation of 258 cm$^2$ V$^{-1}$ s$^{-1}$ across the probe [30]. Also, the transconductance $G_m$ is shown (normalized to each transistor’s CNP), which is defined as the first derivative of $I_{ds}$ over $U_{gs}$. Of crucial importance to any sort of sensor array is the signal-to-noise ratio (SNR) and its homogeneity across recording sites. The SNR in the gSGFET is mainly affected by two physical parameters: the transconductance, which sets the transistor’s sensitivity to signal fluctuations at the gate and the intrinsic device noise integrated over the relevant frequency range $I_{rms}$. A common figure of merit to quantify the gSGFET’s SNR is the $U_{rms}$ value ($I_{rms}/G_m$), which represents the equivalent gate noise below which signals are undetectable. As can be seen, the $U_{rms}$ values of the gSGFETs on the array, are around 40 $\mu$V$_{rms}$ (for the frequency band from 1 Hz to 100 Hz), which allows the detection of local field potentials (typical amplitude above 100 $\mu$V) from the surface of the brain. The distribution across the array of each parameter ($I_{ds}$, $G_m$, $U_{rms}$), calculated at the bias point of highest absolute transconductance (peak–$G_m$), where the device shows lowest $U_{rms}$, is shown in the corresponding color maps. With yields above 90% on a 4-inch wafer (each wafer carrying 14 probes) and large, evenly distributed SNR across all recording sites, the gSGFET technology shows high maturity and homogeneity, which is a key requirement to enable multiplexed addressing schemes.

The most common type of multiplexing is time-division multiplexing (TDM), which refers to a technique of sequentially addressing the columns of a sensor array, while continuously measuring from its rows. Such addressing is normally being achieved by switches, which can be placed either directly on the array or externally [14, 17, 18]. While placing the switches directly on the array has the advantage of reducing inter-site crosstalk it requires complex fabrication of flexible switching technology, as previously mentioned [17]. Complementing arrays of passive sensing elements (i.e. electrodes) with an external addressing configuration is challenging, as their recorded voltage signal is prone to pick up noise; if the preamplifier is placed far from the electrode, additional buffer transistors are required to convert the signal into current and feed it to the read-out circuitry. The use of active sensing elements (i.e. transistors) offers a great benefit here, as they feature an intrinsic voltage-to-current conversion, making the recorded signal more robust to noise. A schematic representation of the addressing and acquisition methodology is shown in figure 1(d). For this purpose, a custom-build PCB board consisting of two main functional blocks has been developed using discrete electronics. One functional block performs the filtering and amplification of the simultaneously acquired AC and DC signals; the other block selects the row to which the bias difference is applied to, using the external switching matrix for addressing. Figure 1(e) illustrates the acquired AC and DC raw input signals for a column of eight gSGFETs and how they can subsequently be used to reconstruct the original signal at each site (figure 1(f)). Resistance mismatch between different transistors leads to current jumps when switching between transistors, which results in the different DC levels in the acquired signal (each gSGFET corresponds to one color in figure 1(e)). The vertical dashed grey line in figure 1(e) indicates the point at which all eight rows were addressed and a new readout cycle begins. At each site a total of 10 points is taken at 100 kHz sampling speed; we discard the first 5 to avoid any switching artefacts and average the rest to a single data point resulting in 1.25 kHz effective sampling rate. It should be here emphasized that array homogeneity carries an additional importance in multiplexed operation owing to two reasons. First, the trade-off between applicable AC signal gain and transistor resistance mismatch; as previously mentioned, current jumps can exceed the dynamic range of the amplifier (indicated in figure 1(e)) leading to saturation and signal loss. Second, the switching artefacts scale with the level of mismatch between devices, requiring longer stabilization times before reliable data points can be collected.

3.2. Scalability and in-vitro assessment

With the goal of creating a high-density, large-scale sensor array, an important discussion to undertake is the one on scalability of this technology. The most important aspects to consider here are the transient response of the transistor, which limits the achievable switching speeds, and the increase of inter-site crosstalk with array size and track resistance. To obtain distortion-free, high-quality recordings in multiplexed operation, it is important to allow sufficient stabilization time after switching, for the transistor to adjust to the changed drain-source bias conditions. This stabilization time is device specific and generally scales with channel length and carrier mobility. Owing to the high carrier mobility of graphene, the transient response of the gSGFET is extremely short (figure 2(a)) compared to other technologies (e.g. transistors based on silicon or conducting polymers) [24]. The ON-state is reached before
1 μs, which is the time resolution of the used measurement equipment (NI DAQ-Card X-Series 6363); for a channel length of 50 μm and a carrier mobility of 2000 cm² V⁻¹ s⁻¹ the actual stabilization time from a time-of-flight estimation is expected to be in the range of hundred nanoseconds. Such fast device stabilization can eventually allow switching speeds beyond 1 MHz (our current configuration is limited by the electronics to 10 kHz). Thus, much larger arrays could be operated this way while maintaining enough sampling speed (>10 kHz) to record even high-frequency activity such as spikes. Due to the solution-gated nature of the device, a small drift occurs during the ON-state of the device which is tentatively associated to the migration of ions when the bias conditions in the channel change under switching. This phenomenon happens at a much slower time scale due to the low ionic mobility; however, it does only create a minor inaccuracy in the measured DC current and does not impact the AC recordings.

As previously stated, the use of external switches bears the disadvantage of not allowing to cut the connections to non-addressed sensors within the array,
which leads to the so-called crosstalk. The lack of on-site switches opens alternative current pathways leading to current contribution from adjacent sites which carry signals from the respective gates and are wrongly attributed to the measured sensor (see figure 2(b)). Such crosstalk can be strongly reduced and, in the ideal case of vanishing track resistance, even fully suppressed by setting the bias point of the non-addressed rows to the same voltage as the data lines, thus preventing any current flow through non-addressed lines [18]. However, in real-world applications the issue of finite track resistance cannot be completely avoided, as the requirements of high sensor density and probe flexibility limit the allowed width and thickness of the metal lines. The presence of these additional resistances create local potential drops, driving current through otherwise suppressed pathways whose amplitude depends on the ratio between track resistance (R_{track}) and transistor resistance (R_{gSGFET}) as well as the number n of columns and rows in the array. To quantify crosstalk in the gSGFET array experimentally, lateral Ag-gates and confined pads of solid polyelectrolyte were placed at each gSGFET of a $2 \times 2$ array by means of inkjet printing (figure 2(c)). This approach allows for selective gate control, which is not possible in a shared liquid electrolyte. Figure 2(d) shows the measured signal at each of the transistors, with a test signal (sine wave of 10 Hz frequency and 30 mV amplitude) only being applied to one of them (black circle in figure 2(c)). Sensors on the same column (red curve in figure 2(d)) or row (dark-red curve in figure 2(d)) as the applied signal are the ones with the largest impact of crosstalk, showing a crosstalk level of $-40$ dB at peak transconductance compared to the signal amplitude.

Diagonally placed sensors (orange curve in figure 2(d)) are much less affected; however, in the latter case the exact level of crosstalk cannot be extracted with accuracy because the signal lies below the floor noise of the electronics. To validate this estimation of the crosstalk, we compared the experimental data with the results obtained from a PSpice simulation of a gSGFET array in which we used a standard p-type MOSFET element tailored to fit the gSGFET’s transfer curve (Figure S2(a)–(b) in supporting information). Figure 2(e) shows the aggregated crosstalk on a single site depending on the track resistance and the array size, assuming identical signals on all remaining sites of the array which sum up to the total crosstalk value. The PSpice model validates the expected near-linear relation with both track resistance and array size. For a $2 \times 2$ array with 20 track resistance and a gSGFET resistance of 1,25 k$\Omega$, both the experiment and the simulation model yield a crosstalk of $-40$ dB. Extrapolating to an array of size $32 \times 32$ (1024 sensors), a crosstalk lower than $-20$ dB can be obtained by reducing the track resistance below 5 or by increasing the resistance of the gSGFET. Such track resistance reduction could be achieved by increasing metal track thickness, using higher number of stacked metal layers and, most importantly, relaxing constraints on probe dimensions. While the ECoG array in this work was designed for application in rodents, which imposes strict size restrictions due to the dimensions of the craniotomy, many other application (e.g. neural probes for large animals or humans) would loosen those significantly.

To validate the fidelity of the gSGFET recordings in the multiplexed operating mode, the recording quality must be compared to the one obtained in steady, non-multiplexed operation. For instance, the rapid switching between devices can potentially increase the noise or generate artefacts in the multiplexed operation mode. Figure 2(f) compares recordings of an artificially generated electrocardiogram signal (ME-W-SG, Multichannel Systems), containing components of different frequencies. The multiplexed and non-multiplexed representation of both test signals are nearly identical, suggesting that the rapid sequential addressing by the multiplexed mode does not generate any visible artefacts, neither in the low nor in the mid frequency band. The root-mean-square value of both recordings is also compared, showing equivalent SNR ratio (figure 2(g)) in both acquisition modes.

3.3. In-vivo validation

Having confirmed the recording fidelity of the gSGFET in the multiplexed operation compared to the standard non-multiplexed acquisition mode, we demonstrate the unimpaired sensitivity of the multiplexed μECoG-array towards biological signals. Electrodiography is primarily used to record local field potentials (LFPs) from the surface of the brain, which originate from spatio–temporal summation of transmembrane–currents generated by synaptic and active conductances, excluding the action potentials [31, 32]. The characteristic spectral content of the LFP signal reflects the time scale of network synchronization and ranges from $<1$ Hz to hundreds of Hz. Figure 3(a) shows a time trace of spontaneous LFP activity in an anesthetized Long Evans rat, recorded in an acute in-vivo experiment using an array of gSGFETs operated in the multiplexed mode (more details in methods section). Under deep anaesthesia, such cortical LFP reflects slow oscillations that are highly coherent across the whole cortical mantle; indeed, no significant differences in signal shape can be seen across all the 64 sensors in the array [33]. To benchmark the recording capabilities of the gSGFET array against other state-of-the-art technologies, a NeuroNexus ECoG array (with 32 circular platinum electrodes of 100 $\mu$m diameter) was simultaneously placed on the opposite hemisphere (figure S3 in supporting information). Figures 3(c) and (d) show recordings and corresponding spectrograms from
Figure 3. In-vivo validation of multiplexed gSGFET µECoG-array: (a) Map of spontaneous LFP activity showing near identical shape across all sites. (b) Map of visually evoked activity averaged over 10 consecutive events (dashed red line indicates timing of optical stimulus; dashed black curves are interpolated values from neighbouring sites for non-functioning sensors. (c) Recording trace derived from AC-coupled passive ECoG-array (NeuroNexus, platinum electrode) as well as DC and AC-filtered gSGFET’s. Note prominent infraslow oscillations (0.1–0.4 Hz), which are not visible in the AC electrode recordings. (d) Corresponding spectrograms of both, NeuroNexus and gSGFET recordings. (e) Visually evoked response recorded on a single sensor (dashed grey box in (b), with an ON- and OFF-response of 50 ms delay and 500 µV peak amplitude. (f) Array maps displaying the distribution of amplitude and time-delay of the ON-peak response across all sites. While the shortest delay is measured for the sensors placed directly on the primary visual cortex (V1), the highest peak–amplitude is seen in the secondary visual cortex (V2). (g) DC–signal (blue, lowpass-filtered below 20 Hz) and AC signal (red, bandpass-filtered between 1–20 Hz) of a single gSGFET during the cortical spreading depression (CSD). A strong DC shift of −15 mV occurs simultaneously with a silencing of high-frequency activity, which is characteristic for a CSD. Corresponding spectrogram of CSD event to validate the silencing. (h) Array map showing the propagating front of the spreading depolarization wave across the array from the right upper to the left lower corner.

an electrode and a gSGFET, displaying the expected synchronicity in activity of both hemispheres. Filtering the signals from 0.1 Hz to 200 Hz (dark-blue and red curve in figure 3(c)), a clear difference in signal shape can be noticed. This difference reflects the high-pass filter of the AC-coupled headstage used for passive ECoG recordings (see Experimental Section), which is necessary to prevent amplifier saturation due to drifts; also the high impedance of passive ECoG electrodes at low frequency leads to reduced gain in such signals, which results in an attenuation of the infraslow frequency content in the LFP signal [23].
Removing these low-frequency components from the gSGFET signal (green curve in figure 3(c)), it is possible to validate that both technologies show very similar recordings of the LFP activity as can also be seen in the corresponding spectrograms.

Visually evoked LFP activity exhibits a well-defined spatial topography and thus can be used for validating the mapping capabilities of the multiplexed gSGFET technology [34]. Figure 3(b) shows the averaged response over 10 consecutive evoked events recorded with an array of gSGFETs in the multiplexed mode. Visually evoked activity typically exhibits a clear response with a delay of 40 ms after both the ON- and OFF-switching of the stimulus (figure 3(e)). The recordings show a main peak (ON response) lasting until 70 ms after the stimulation with and peak amplitude of 500 µV. Hence, signal shape and amplitude are in nice agreement with previously reported results of non-multiplexed gSGFETs [21]. Further, figure 3(f) presents the spatial distribution of both amplitude and time-delay of the ON-peak. The earliest response is detected on the lower end of the array which represents sensors directly placed on the primary visual cortex (V1) where the activity originates, and spreads then radially towards other higher visual cortical areas. However, highest peak-amplitude is measured in the centre-left region (secondary visual cortex, V2) which likely reflects a different magnitude and proximity current dipole, that gives rise to the surface LFP (LGN input to L1V in V1 vs V1 input to L2/3 pyramidal cells in V2) [35].

In addition, to its capability to record LFPs, the gSGFETs exhibit a unique sensitivity towards slow and infra-slow (below 0.1 Hz) signals, which in the case of passive electrode recordings are hidden by baseline drifts and the impedance-related loss of gain at low frequency [23]. In order to confirm that multiplexed acquisition preserves signal quality in this frequency band, we have investigated recordings of a cortical spreading depression (CSD). CSDs emerge due to a cellular depolarization of neurons and astrocytes which is associated to brain injury and migraines among others [36]. Here, the CSD was artificially triggered by injecting KCl into the cortex that caused a slowly propagating wave moving across the cortex. Figure 3(g) depicts the recording of a gSGFET in the array. The DC component of the signal shows the characteristic large shift of 15 mV amplitude. The AC component and its corresponding spectrogram (figure 3(h)) reveals a silencing of the high-frequency activity during the event, caused by the cellular depolarization and which is characteristic for the CSD. The maps below (figure 3(i)) show the respective position of the depolarising wave at different times after KCl injection, moving from the top right to the bottom left at about 7 mm per minute speed.

4. Conclusion

This work demonstrates the compatibility of graphene solution-gated field-effect transistors (gSGFETs) with time-division multiplexed acquisition mode, utilizing a strongly simplified addressing concept to overcome the hurdle of excessively complex device fabrication. The superiority of graphene over silicon and organic polymers for high-speed applications makes the gSGFET an ideal device for multiplexed sensor arrays. In-vitro and in-vivo assessments confirm the fidelity of broad-band signal representation (infra-slow oscillations and local field potentials) in multiplexed operation, with signal quality comparable to the state-of-the-art of commercially available neuro-sensors. Consequently, next to their potential as efficient transducers of neural activity, gSGFETs show great promise as a building block for multiplexed brain-machine interfaces of high sensor count. Thus, this work represents an important cornerstone in the development of large-scale, flexible gSGFET µECOG arrays capable of providing high resolution mappings of neural activity to control neuroprosthetics and to help exploring the operation and functionalities of the brain.

This work has made use of the Spanish ICTS Network MICRONOFABS partially supported by MICINN and the ICTS ‘NANBIOSIS’, more specifically by the Micro-NanoTechnology Unit of the CIBER in Biotechnology, Biomaterials and Nanomedicine (CIBER-BBN) at the IMB-CNM. GG and SS thank financial support from the MINECO/FEDER CTQ2015-65439-R project. SS is supported by FEDER funds managed by the Catalan Secretary of Universities and Research through project PROD-0000114 (Enterprise and Knowledge, Industry Department, Generalitat de Catalunya).
