ABSTRACT

Evidence of triggered star formation at large spatial scales involving stellar clusters is scarce. We investigate a Galactic region ($l = 130^\circ, b = 0^\circ35$) populated by several open stellar clusters that according to the last GAIA data release, are located at a distance of about 2.9 kpc. By analyzing the interstellar medium (ISM) at infrared, centimeter, and millimeter wavelengths towards this group of clusters we discovered a shell of material of about 2° in size at the same distance. We suggest that the shell, mainly observed at 12 µm and in the HI emission at 21 cm, was generated by the action of massive stars belonging to clusters Berkeley 7 and UBC 414, that lie at its center. Five clusters (MWSC0152, Czernik 6, Czernik 7, Berkeley 6, NGC 663, and NGC 654) lie at the border of this shell. From the comparison between the dynamical time of the discovered HI shell and the analysis of the ages of stellar populations in these clusters, we conclude that the expansion of the shell could have triggered in the past the formation of stars in some of them. We point out that in order to find physical evidence supporting a genetic connection between stellar clusters, it is necessary not only to study the individual clusters and their stellar populations, but also to investigate their surrounding ISM at a large spatial scale.

Key words: galaxies: star clusters: general – stars: massive – stars: formation – ISM: structure

1 INTRODUCTION

Triggered star formation has been extensively studied in the past decades and it was mainly proved at the interfaces between HII regions and molecular clouds. Populations of new stars are usually observed in molecular clouds that surround the photodissociation regions, showing that the expansion and the radiative action of the HII regions can trigger the formation of new stars (e.g. Figueira et al. 2020; Duronea et al. 2017; Deharveng et al. 2015; Zavagno et al. 2010, 2007; Hosokawa & Inutsuka 2005). These processes can be studied towards relatively young regions, with at most a few $10^5$ yr, and within spatial scales between 1 to 10 parsecs.

Triggered star formation due to cloud-cloud collisions has received special attention since some years ago, and evidences supporting such process have been found (e.g. Fukui et al. 2021; Dobbs et al. 2020, and references therein). The magnetic field amplified by the shock compression in the cloud-cloud collision can explain massive-cores and star formation in the collision interface (Inoue & Fukui 2013; Inoue et al. 2018). This process can take place at different spatial scales, from that of the typical HII bubbles to larger spatial scales ranging from a few tens to hundreds of parsecs, and the involved time scales in the formation of massive stars can be within 1 Myr after the shock (Inoue et al. 2018; Fukui et al. 2018).

When the spatial and temporal scales become even larger, studying triggered star formation events becomes challenging. It is known that large star-forming complexes produce stellar associations and star clusters. The pressure of young stars trigger gas accumulation on the periphery of cleared cavities in the interstellar medium (ISM), which often take the form of rings where new groups of stars form (Elmegreen 2012). At large spatial scales, this kind of rings are usually observed as atomic shells or supershells with sizes that go from tens to hundreds of parsecs, and even kiloparsecs (McClure-Griffiths et al. 2002). They can contribute to enhance the amount of molecular matter in the volumes affected by their expansion as theoretically proposed by for example Inoue & Inutsuka (2009) and Heitsch & Hartmann (2008), and new stars, or young clusters, can form from this molecular matter (Dawson et al. 2011). Over time, the stellar population of these clusters evolves, and the parental molecular clouds disperse (Fukui et al. 1999). Hence, looking for hierarchical triggered star formation...
formation at large spatial scales, and considering times scales ranging from some tens to hundreds of Myr, typical of intermediate-age open clusters, is challenging, and thus, it is necessary to make efforts in order to find causal connections among clusters and clusters complexes (e.g. de la Fuente Marcos & de la Fuente Marcos, 2020). This kind of studies are important because connecting such processes at large spatial and time scales allows us to better understand the dynamics and evolution of the Galaxy.

Evidence of triggered star formation among evolved or intermediate-age stellar clusters is rare. Indeed, besides studying the spatial location, distances, dynamics, and ages of such stellar clusters, we argue that it is mandatory to study the ISM around them with the aim to find pieces of physical evidence that suggest a present or an old connection that gives support, or at least allows us to infer, the presence of relics of triggered star-forming processes. In the following sections, based on the study of the ISM, cluster parameters and their stellar populations, we present observational evidence supporting a genetic relation within a group of Galactic open clusters.

### 2 PRESENTATION OF THE CASE

We focus on a Galactic region centered at \(l = 130^\circ, b = 0^\circ\) with a radius of \(1.5\) pc, that according to Kharchenko et al. (2009) and Cantat-Gaudin et al. (2013) is populated by several open stellar clusters. Table 1 presents the coordinates, distances, and ages corresponding to these clusters. Following the mentioned authors, we find that most of them are located at a distance lying in the range of about 2.4–3.1 kpc (see columns labelled as CG and K), suggesting that they could be located close enough to be physically related.

Given that the GAIA Early Data Release 3 (GAIA EDR3, Gaia Collaboration et al. 2020) has been recently made available, for each of the clusters in Table 1, we consider the cluster members given by Cantat-Gaudin et al. (2020), when available, or by Kharchenko et al. (2013), and calculated the mean value of GAIA EDR3 parallaxes, considering those stars with G brighter than 15 mag, which ensures small parallax errors.

### 3 DATA

To study the ISM towards this region populated of stellar clusters we analyzed data from three large-scale databases. We used IR data extracted from the Wide-field Infrared Survey Explorer (WISE; Wright et al. 2010). To study the distribution of cold gas towards the region we used HI data retrieved from the Canadian Galactic Plane Survey (CGPS; Taylor et al. 2003), which have an angular and spectral resolutions of \(1^\prime\) and 0.8 km s\(^{-1}\), respectively, and \(^1\)CO \(J=1\rightarrow0\) emission obtained from Five College Radio Astronomical Observatory (FCRAO) CO Survey of the Outer Galaxy (Heyer et al. 1998) with 45" and 0.8 km s\(^{-1}\) in angular and spectral resolution.

### 4 RESULTS

In the following sections we present the results obtained from each dataset, with the aim of investigating a physical connection among some of the mentioned stellar clusters.

#### 4.1 IR emission

Figure 1 shows the 12 \(\mu\)m emission towards the analyzed region conformed by eight mosaics obtained from the WISE database. Stellar clusters in the distance range of about 2.9 to 3.1 kpc are included. A shell-like structure with an elliptical morphology, centered close to the clusters Berkeley 7 and UBC 414 can be observed. The clusters NGC 654, NGC 633, and Berkeley 6 are located over the bulk of IR emission that constitutes the south-southwest portion of the shell, while clusters Czernik 7, Czernik 6, and MWS0152 lie towards the north-northeast border which is more diffuse. This shell has many interesting features (some of them are discussed below), and its emission at 12 \(\mu\)m should be due to the presence of polycyclic aromatic hydrocarbons (PAHs) and dust grains (e.g. Reach et al. 2017), that absorbs UV photons and are heated by the radiation of massive stars. This scenario is compatible with the fact that Berkeley 7 and/or UBC 414 has/have emptied the ISM at its surroundings through the radiation and winds of its stellar members, and likely generated the observed IR shell. The expansion of this shell could have affected some of the clusters located at its border. This issue is studied in the following sections.

Figure 2 presents a WISE three-colour image remarking two
conspicuous structures as seen at IR: a complex of pillar-like features towards the southeast of Berkeley 7, and a cometary nebula close to the same cluster. It is well known that this kind of structures are generated by the action of massive stars (e.g. Mookerjea et al. 2019; Djupvik et al. 2017; Gahm et al. 2006), which through their ionizing and photodissociation shock fronts compress and shape the material that surrounds them. Dense and dusty molecular clumps are usually shaped in pillars of gas pointing toward the ionizing sources, and in globules detached from the parental molecular cloud. Cometary globules are small and dense clouds consisting of a dense head, surrounded by a bright rim, and prolonged by a diffuse tail. Thus, the features remarked in Fig. 2 are evidence supporting the presence of massive stars in the region.

### 4.2 Molecular gas

Regarding the molecular gas distribution, we inspected the CO data cube along the whole velocity range and we found some CO emission likely related to the shell observed at IR in the velocity range that goes from $-27$ to $-42$ km s$^{-1}$ (see Fig. 3). The CO spectra corresponding to the western molecular feature peak at about $-37$ km s$^{-1}$ (see Fig. 4). Using the rotation curve of Reid et al. (2014), this velocity yields a distance of about 2.8 kpc for the observed molecular cloud in perfect agreement with the distance range in which the stellar clusters lie.

Figure 3 shows that the observed molecular clouds have a good morphological correspondence to the IR emission towards the west of the shell. In addition, a molecular fragment is observed eastwards Berkeley 6, and a small molecular clump appears exactly at the head of the cometary nebula described above. This integrated $^{12}$CO map shows that the pillar-like features lack of molecular gas. However, by inspecting the spectra corresponding to this region we find a weak emission at $-33$ km s$^{-1}$ (see Fig. 5) related to the pillars. While this marginal signal suggests that the molecular gas was highly photodissociated in this region, its systemic velocity and the spatial association with the pillars show that they are indeed located at the same distance of the analyzed complex, and thus they should be sculpted by the action of the stars that have generated the shell observed at the IR wavelengths.

The rest of the IR shell lacks of molecular gas. This is con-
sistent with a molecular shell fragmented and partially destroyed by the radiation and winds from massive stars, and probably also by supernova explosions (Zubovas et al. 2014). The molecular feature lying towards the west may be result of the densest region of a molecular shell that was not completely destroyed yet. Moreover, the clumpiness in the observed molecular structures supports the scenario in which the fragmentation of a molecular cloud with a shell morphology leads the formation of stars and possibly stellar clusters (Klessen 2001).

To characterize the most conspicuous molecular features we calculate the H$_2$ column density using the relation: $N(H_2) = X \int T(CO) dv \ cm^{-2}$, where $X = 1.9 \times 10^{20}$ (K km s$^{-1}$)$^{-1}$ (Digel et al. 1995), and the mass from: $M = 2m_{HI}d^2 \Omega \sum_i N_i(H_2)$, where $m_{HI}$ is the H atom mass, $d = 2.8$ kpc, and $\Omega$ the beam area of the CO data. The summation was performed over the area delimited by the 2 K km s$^{-1}$ contour. Hence, the mass values obtained for the western molecular large feature and the small cloud observed between the clusters Berkeley 6 and Czernik 5 are $9.3 \times 10^4$ and $1.0 \times 10^2$ M$_\odot$, respectively. Additionally, the mass of the small clump ($\ell$’ in radius) related to the head of the cometary nebula was calculated in 170 M$_\odot$.

### 4.3 Neutral atomic gas

After a careful inspection of the H$_i$ data cube we found an interesting structure extending from $-28$ to $-36$ km s$^{-1}$ (see Fig. 6). This shell-like H$_i$ feature with an elliptical morphology (semi-axes of 0’8 and 1’2) appears centered close to the position of Berkeley 7 and has a perfect morphological correspondence with the structure observed at the IR emission, mainly towards the southwest. Indeed, this kind of H$_i$ features is a typical galactic structure classified as H$_i$ shell (e.g. McClure-Griffiths et al. 2002; Relano et al. 2007), which are massive objects, usually detected as voids in the neutral hydrogen emission as is the case. It is known that they are formed through the combined effects of stellar winds and supernovae, ionizing the neutral medium and sweeping up a massive expanding shell. Thus, in this case, it is very likely that the H$_i$ shell was generated by the action of stars located at its interior, and probably, some, or most of them, belonging to Berkeley 7 and/or UBC 414. Moreover, the velocity range in which the H$_i$ shell extends is in agreement with that of the molecular features, showing that the H$_i$ shell is located at the same distance as the molecular clouds, in coincidence with the distance of the stellar clusters included in the figures.

### 4.4 Kinetic energy stored in the H$_i$ shell

Firstly we calculate the H$_i$ column density from the typical equation: $N(H_i) = 1.823 \times 10^{18} f_{HI} T_B dv \ cm^{-2}$, where $v_1$ and $v_2$ are $-28$ and $-36$ km s$^{-1}$, the velocity range along with the shell extends, and $T_B$ is the brightness temperature. Then, the gaseous mass associated with the H$_i$ shell was obtained from a similar expression as used in the estimation of the molecular mass (Sect.4.3). In this case, the summation was done over all the area delimited by 280 K
is also considered, the kinetic energy stored in the shell

\( E_{\text{kin}} = 0.5 \, M \, v_{\text{exp}}^2 \) yielding an energy of
5 \times 10^{49} \text{ erg}. If the mass of the molecular clouds described in
Sect. 4.3 is also considered, the kinetic energy stored in the shell
is about 8.3 \times 10^{49} \text{ erg. Regarding the involved errors, considering
a conservative error in the distance of 10%, an error of about 20% is
derived for the kinetic energy stored in the shell, which yields an
upper value of \( E_{\text{kin}} = 1 \times 10^{50} \text{ erg}. The mass value and the \( E_{\text{kin}} \)
are consistent with others H\text{I} shells studied in the literature (e.g.
McClure-Griffiths et al. 2002; Suad et al. 2016).

Additionally, defining the dynamic age of the structure as
\( t_{\text{dyn}} = R_{\text{eff}} / v_{\text{exp}} \), which is a rough estimate of the time along which
the energy was injected in the shell to form it, where \( R_{\text{eff}} = 47.5 \text{ pc

Figure 7. Channel maps of the H\text{I} emission (grays) and the \(^{12}\text{CO} J=1–0\) emission (red contours) from
\(-27.8 \text{ to } -33.6 \text{ km s}^{-1}\) each \( \sim 0.8 \text{ km s}^{-1} \). The
colourbar is presented at the first panel and is in K, and the \(^{12}\text{CO} \) contours levels are: 0.65, 1.50, 2.50, and 4.0 K. The positions of the clusters are indicated
and the blue dashed ellipse remarks the H\text{I} shell.

Figure 8. Same as Fig. 7 but in the velocity interval \(-34.4 \text{ to } -40.2 \text{ km s}^{-1}\), and with a different range in the grayscale (see the colourbar presented at the first panel).
is the effective radius of the shell \(R_{\text{eff}} = \sqrt{a b}\), where \(a\) and \(b\) are the semi-axes of the ellipse, we obtain \(t_{\text{dyn}}\) about 11 Myr.

4.5 The origin of the shell

In this section, we analyse whether the origin of the shell can be attributed to the action of stellar winds of massive stars located within the shell, eventually belonging to Berkeley 7 and/or UBC 414 clusters.

Firstly, we notice that the galactic Cartesian coordinates of both clusters (Cantat-Gaudin et al. 2020), indicate that their centers are separated only 69 pc, which is within the typical spatial linking length of open cluster pairs (100 pc, Conrad et al. 2017). Such small physical separation, together with their similar mean proper motions, could indicate a possible common origin or physical interaction between Berkeley 7 and UBC 414, and certainly deserves further studies, but is beyond the scope of the present article.

The open cluster Berkeley 7 lies at the center of the shell, and according to Cantat-Gaudin et al. (2020) it has an age of 34 Myr. The authors list 89 stars as possible members of Berkeley 7, which according to their GAIA magnitudes, their age, their distance, and considering E(B-V)=0.7 (Molina Lera et al. 2018) are in the range 1.3 M⊙ to around 9 M⊙, following GENEVA rotating isochrones (Ekström et al. 2012), reddened considering the laws given by Gaia Collaboration et al. (2018). The two brightest stars of the cluster are LS I +62 191 and LS I +62 190, classified as B1 VIII and B2 V respectively, by Molina Lera et al. (2018). The third brightest star, TYC 4036-1237-1, has not been assigned a spectral type yet, but its position in the colour-magnitude diagram, very close to LS I +62 190, points to the same spectral type, B2 V.

UBC 414 is a recently detected open cluster (Castro-Ginard et al. 2020), gathering 29 confirmed stellar members, with age and distance similar to those of Berkeley 7: 30 Myr and 2.9 kpc. Considering these cluster parameters and Geneva isochrones (Ekström et al. 2012), reddened considering the laws given by Gaia Collaboration et al. (2018), we find E(B-V)=0.55. According to this isochrone, only the four brightest objects have masses larger than 7 M⊙, and could blow stellar winds. These stars are TYC 4036-1373-1 (G=10.94), EM' GGA 128 (G=1.156), TYC 4036-999-1 (G=11.98), TYC 4036-2029-1 (G=12.09). Among them, only EM' GGA 128 has been studied in the past, though not thoroughly, and was assigned a spectral type OBe by Hardorp et al. (1959). Being similar in distance and age, the 4 brightest stars in UBC 414 seem to be of similar spectral type as those of Berkeley 7, around B2 V or earlier.

Therefore, we can consider that at least these seven B2 V stars could have contributed to the generation of the Hi shell. Following Leitherer et al. (1992) and Lamers & Leitherer (1993), we use a mass loss rate and a wind velocity of \(M = 10^{-8.8}\ M_\odot\ yr^{-1}\) and \(v_w = 2200\ km\ s^{-1}\), typical values for a 10 M⊙ star, to calculate its wind energy from \(E_w = 0.5 M v_w^2 \tau\). Assuming \(\tau\) about 30 Myr, the age of the clusters, we obtain \(E_w = 1.6 \times 10^{50}\ erg\) injected by the seven 10 M⊙ stars, which is clearly not enough to control the kinetic energy stored in the Hi shell (see Sect. 4.4). Moreover, using the dynamic age of the Hi shell as \(\tau\), \(E_w\) is even lower. However it is pretty plausible that other undetected massive stars lie, or have lied, in the region. For instance, three O7V or ten O9V stars would produce a wind energy of about \(4.2 \times 10^{50}\ erg\), and considering a theoretical energy conversion (\(\eta = E_w/E_v\) of 0.2 (Weaver et al. 1977), they could explain the kinetic energy stored in the shell.

By assuming an initial mass function (IMF), we can roughly estimate the population of massive stars that clusters Berkeley 7 and UBC 414 could have harbored. We consider a typical IMF with \(N(M) = N_0 M^{-2.35}\) (Salpeter 1955; Kroupa 2001), the ages and distances of Berkeley 7 and UBC 414, and isochrones of Ekström et al. (2012), and we assume that the present day observed number of stars (that correspond to the mass range \(1.21 – 9.1\ M_\odot\)) is representative of that of the IMF. Under these assumptions, the number of stars with masses larger than 9.1 M⊙ at the ZAMS for Berkeley 7 is 6, and for UBC 414 is 2.

Then, we estimate that besides the seven massive stars described above, the clusters Berkeley 7 and UBC 414 together could have had about eight stars with \(M > 9\ M_\odot\) in the past. These stars could have contributed to the generation of the Hi shell, and moreover, some of them could have exploded as a supernova and injected mechanical energy through their shock fronts (e.g. Normandeau et al. 2000; Relaño et al. 2007; Hennebelle & Iffrig 2014). Additionally, we cannot discard that this shell can be a remnant of a past cloud-cloud collision event, which, as several authors propose, may be efficient in star formation (Fukui et al. 2021 and references therein).

In the following section, we explore whether the expansion of the shell could affect the stellar population of the clusters located at its borders.

5 RELATING THE SHELL AND THECLUSTERS

The two youngest clusters located over the shell-like structure are MWS0152 and NGC 654 with about 4 and 10 Myr old, respectively. Taking into account the shell dynamical time of about 11 Myr, we suggest that the formation of the stars belonging to these clusters could be triggered by the expansion of this shell (Elmegreen 2002, 2012). Moreover, in the case of NGC 654, it is interesting to note that the cluster is related to a molecular clump, showing that the parental molecular cloud has not been completely dispersed yet.

The oldest cluster of the group is Czernik 7 (about 1000 Myr). Given to its age and that it is probably located at a farther distance, it is unlikely a dynamical association with the shell. Another old cluster, but in this case very likely related to the shell, is Berkeley 6, with 220 Myr. Based on its age and the low amount of stellar members (79 stars, according to Cantat-Gaudin et al. 2018) it is unlikely that star formation induced by the shell expansion has occurred within it.

Finally, Czernik 6 and NGC 663 appear to have ages similar to those of Berkeley 7 and UBC 414, around 30 Myr, and it is possible that they have been affected by the expansion of the shell. While Czernik 6 hosts only a few tens of stars, the open cluster NGC 663 has more than 620 members (Cantat-Gaudin et al. 2018). Then, this cluster is massive enough to explore a possible scenario of triggered star formation favoured by the expansion of the shell due to the action of Berkeley 7/UBC414. Certainly, NGC 663 lies in a region very bright at 12 μm (see Fig. 1), showing the presence of abundant dust which supports a scenario of star formation.

In order to study possible different stellar populations within NGC 663, we investigate the kinematical properties of the stellar members using the new GAIA EDR3 data, which provides improved proper motions. By considering as cluster members of NGC 663 those objects with cluster membership probability larger than 0.5 according to Cantat-Gaudin et al. (2018), we obtain GAIA EDR3 mean values for the cluster position RA: 26°57079, dec. 61°2164, a cluster distance of 2912 pc (corresponding to the median of parallax values of 0.34345) or 2926 pc (mean value of in-
and we considered rotating isochrones for rotating populations (Ekström et al. 2012), corresponding to the age of the cluster quoted in the literature (30 Myr, see Table 1), with two different colour excesses: 0.75 (dotted line) and 0.85 (dashed line), typical intra-cluster excesses given in the literature for NGC 663 (e.g. Phelps & Janes 1994). Interestingly, stars with \( \mu_r < 0 \) seem to be younger than those with \( \mu_r > 0 \), with an isochrone age around 10 Myr (red curves).

Figure 9. GAIA DR2 CMD of the central part of NGC 663, the most densely populated region where half of the stars are located. We plot stars with \( \mu_r < 0 \) (red) and \( \mu_r > 0 \) (blue). Blue curves indicate Geneva isochrones for rotating populations (Ekström et al. 2012), corresponding to the age of the cluster quoted in the literature (30 Myr, see Table 1), with two different colour excesses: 0.75 (dotted line) and 0.85 (dashed line), typical intra-cluster excesses given in the literature for NGC 663 (e.g. Phelps & Janes 1994). Interestingly, stars with \( \mu_r < 0 \) seem to be younger than those with \( \mu_r > 0 \), with an isochrone age around 10 Myr (red curves).

We investigated a Galactic region \( l = 130^\circ, b = 0^\circ 35 \) populated by several open stellar clusters. We noticed that most of the clusters in the region (MWSC0152, Czernik 6, Berkeley 6, NGC 663, NGC 654, Berkeley 7, and UBC 414) are located almost at the same distance (about 2.9 kpc), and also the distance of Czernik 7 can be considered close to 3 kpc. Given that clusters Berkeley 7 and UBC 414 appear at a position around which the other clusters are distributed quite equidistantly, we studied the ISM in order to search for some evidence pointing to a connection among them.

By analyzing the ISM at IR, centimeter, and millimeter wavelengths we discovered a shell of interstellar material in whose borders the clusters MWSC0152, Czernik 6, Czernik 7, Berkeley 6, NGC 663, and NGC 654 lie. From the mid-IR emission we found some interesting features such as pillars and globules strongly suggesting an interaction between the radiation from massive stars and molecular gas. From the kinematical analysis of the H\( \alpha \) and CO emissions we found that the shell is located at the same distance as the clusters, and it has a mass of about \( 3 \times 10^5 \) M\(_\odot\). We estimated that the kinetic energy stored in the shell is in the range \( (0.8 - 1.0) \times 10^{38} \) erg, and its dynamical age is about 11 Myr. We point out that it is very likely that massive stars belonging to Berkeley 7 and UBC 414 and/or supernova events occurred in these clusters have generated this shell and influenced the stellar population of the clusters lying at its borders.

By comparing the ages of the shell and the clusters, we suggest that the expansion of the shell could have triggered the formation of the stars of MWSC0152 and NGC 654. In the case of the latter, the youngest among all the clusters in the region, it is important to note that it is still related to a molecular cloud, supporting a triggered star formation scenario in which the parental molecular cloud has not been dispersed yet. Cluster NGC 663 was of particular interest. We discovered that this cluster contains two different stellar populations regarding their ages: a group of stars with about 30 Myr old, and another group with about 10 Myr, strongly suggesting that the expansion of the shell triggered the formation of this second group.

In this work we presented solid evidences pointing to probe triggered star formation among stellar clusters at large spatial scales, and it motivates further studies to other stellar clusters groups in order to find a genetical connection among them.

6 SUMMARY AND CONCLUDING REMARKS

We investigated a Galactic region \( l = 130^\circ, b = 0^\circ 35 \) populated by several open stellar clusters. We noticed that most of the clusters in the region (MWSC0152, Czernik 6, Berkeley 6, NGC 663, NGC 654, Berkeley 7, and UBC 414) are located almost at the same distance (about 2.9 kpc), and also the distance of Czernik 7 can be considered close to 3 kpc. Given that clusters Berkeley 7 and UBC 414 appear at a position around which the other clusters are distributed quite equidistantly, we studied the ISM in order to search for some evidence pointing to a connection among them.

By analyzing the ISM at IR, centimeter, and millimeter wavelengths we discovered a shell of interstellar material in whose borders the clusters MWSC0152, Czernik 6, Czernik 7, Berkeley 6, NGC 663, and NGC 654 lie. From the mid-IR emission we found some interesting features such as pillars and globules strongly suggesting an interaction between the radiation from massive stars and molecular gas. From the kinematical analysis of the H\( \alpha \) and CO emissions we found that the shell is located at the same distance as the clusters, and it has a mass of about \( 3 \times 10^5 \) M\(_\odot\). We estimated that the kinetic energy stored in the shell is in the range \( (0.8 - 1.0) \times 10^{38} \) erg, and its dynamical age is about 11 Myr. We point out that it is very likely that massive stars belonging to Berkeley 7 and UBC 414 and/or supernova events occurred in these clusters have generated this shell and influenced the stellar population of the clusters lying at its borders.

By comparing the ages of the shell and the clusters, we suggest that the expansion of the shell could have triggered the formation of the stars of MWSC0152 and NGC 654. In the case of the latter, the youngest among all the clusters in the region, it is important to note that it is still related to a molecular cloud, supporting a triggered star formation scenario in which the parental molecular cloud has not been dispersed yet. Cluster NGC 663 was of particular interest. We discovered that this cluster contains two different stellar populations regarding their ages: a group of stars with about 30 Myr old, and another group with about 10 Myr, strongly suggesting that the expansion of the shell triggered the formation of this second group.

In this work we presented solid evidences pointing to probe triggered star formation among stellar clusters at large spatial scales, and it motivates further studies to other stellar clusters groups in order to find a genetical connection among them.

ACKNOWLEDGEMENTS

We acknowledge the anonymous referee for her/his useful comments. M.B.A. is a doctoral fellow of CONICET, Argentina. S.P. and A.G. are members of the Carrera del Investigador Científico of CONICET, Argentina. A.G. acknowledges the financial support received from the Agencia Nacional de Promoción Científica y Tecnológica of Argentina (PICT2017-3790). This work has made use of data from the European Space Agency (ESA) mission Gaia (https://www.cosmos.esa.int/gaia), processed by the Gaia Data Processing and Analysis Consortium (DPAC, https://www.cosmos.esa.int/web/gaia/dpac/consortium). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the Gaia Multilateral Agreement.
