Maximum Entropy Differential Dynamic Programming

Oswin So, Ziyi Wang and Evangelos A. Theodorou

Abstract—In this paper, we present a novel maximum entropy formulation of the Differential Dynamic Programming algorithm and derive two variants using unimodal and multimodal value functions parameterizations. By combining the maximum entropy Bellman equations with a particular approximation of the cost function, we are able to obtain a new formulation of Differential Dynamic Programming which is able to escape from local minima via exploration with a multimodal policy. To demonstrate the efficacy of the proposed algorithm, we provide experimental results using four systems on tasks that are represented by cost functions with multiple local minima and compare them against vanilla Differential Dynamic Programming. Furthermore, we discuss connections with previous work on the linearly solvable stochastic control framework and its extensions in relation to compositionality. Link to Video.

I. INTRODUCTION

Existing methods for trajectory-optimization solve the optimization problem by iteratively relying on local information via derivatives [1, 2]. Dynamic Programming (DDP) [3, 4] is a popular trajectory optimization method for nonlinear systems used in model-based Reinforcement Learning (RL) and Optimal Control problems, where the problem is iteratively solved via second order approximations of the cost and dynamics. With stage-wise positive Hessian matrices, DDP enjoys quadratic convergence [5]. However, these methods usually only guarantee convergence to a local minimum and are unable to reach better local minima once converged. In cases where there are dynamic obstacles, the cost landscape can be highly nonconvex with suboptimal local minima that are unsatisfactory. Methods that try to address this problem include random restarts [6] or via topological approaches that explicitly consider the homotopy classes of trajectories [7, 8].

Maximum entropy is a technique widely used in RL and Stochastic Optimal Control (SOC) to improve the robustness of stochastic policies. Performance robustness is achieved through an additional entropy regularization term in the cost function that improves exploration by discouraging policies from converging to a delta distribution over the current optimal control [9, 10]. In RL, Soft Actor Critic uses a maximum entropy formulation of the Differential Dynamic Programming algorithm and derive two variants using unimodal and multimodal Gaussian policies. Finally, we compare the performance of both proposed algorithms against vanilla DDP on 2D Point Mass, 2D Car, Quadcopter and Manipulator in simulation.

The main contributions of this work are threefold:

• We derive the Bellman equation for the discrete time MEOC problem.
• We propose Maximum Entropy DDP (ME-DDP) and Multimodal Maximum Entropy DDP (MME-DDP) to improve exploration over vanilla DDP.
• We showcase the benefit of the improved exploration of ME-DDP and MME-DDP over vanilla DDP in converging to better local minima on four different systems in simulation.

II. MAXIMUM ENTROPY BELLMAN EQUATION

Standard discrete-time deterministic optimal control problems minimize the cost over time horizon \((0, 1, \cdots, T)\)

\[
J(u) := \Phi(x_T) + \sum_{t=0}^{T-1} l_t(x_t, u_t),
\]

where \(l_t\) and \(\Phi\) are the running and terminal costs respectively. The state and control trajectories, \((x_t)_{t=0, \cdots, T}, x_t \in \mathbb{R}^{n_x}\) and \((u_t)_{t=0, \cdots, T-1}, u_t \in \mathbb{R}^{n_u}\), satisfy deterministic dynamics

\[
x_{t+1} = f(x_t, u_t).
\]

In this work, we take a relaxed control approach and consider a stochastic control policy \(\pi_t(u_t|x_t)\) with the same deterministic dynamics as in (2). In addition, we introduce an entropy term to the original objective (1)

\[
J_\pi := \mathbb{E}_\pi \left[ \Phi(x_T) + \sum_{t=0}^{T-1} \left( l_t(x_t, u_t) - \alpha H[\pi_t] \right) \right],
\]

where \(\alpha > 0\) is an inverse temperature term, the expectation is taken with respect to \(u \sim \pi(-|x)\), and \(H[\pi]\) is the Shannon entropy of \(\pi\) defined as

\[
H[\pi] = -\mathbb{E}_\pi[\ln \pi] = -\int \pi(u) \ln \pi(u) \, du.
\]
For this problem formulation and the standard value function definition of \( V(x) = \min_{\pi} J(x, \pi) \), the Bellman equation takes the form

\[
V(x) = \inf_{\pi} \left\{ \mathbb{E}_x \left[ l(x, u) + V'(f(x, u)) \right] - \alpha H[\pi] \right\}, \tag{5}
\]

In (5) and below we omit the time index \( t \) for nonterminal times for simplicity and use \( V'(f(x, u)) \) to denote the value function at the next timestep.

Solving (5) results in a Gibbs distribution for \( \pi^* \) [14, 16]. The form of \( \pi^* \) and \( V \) are presented in the following lemma.

**Lemma 1.** The optimal policy \( \pi^* \) solving the infimum in (5) is the Gibbs distribution

\[
\pi^*(u|x) = Z^{-1} \exp \left( -\frac{1}{\alpha} \left[ V'(f(x, u)) + l(x, u) \right] \right), \tag{6}
\]

where \( Z \) denotes the partition function

\[
Z(x) = \int \exp \left( -\frac{1}{\alpha} \left[ V'(f(x, u)) + l(x, u) \right] \right) du. \tag{7}
\]

Consequently, the value function \( V \) takes the form

\[
V(x) = -\alpha \ln Z(x). \tag{8}
\]

We refer the readers to Appendix A in [17] for a proof of Lemma 1.

### III. Maximum Entropy DDP

We will now use DDP to solve the MEOC problem and derive the ME-DDP algorithm. For notational simplicity, we will drop the second-order approximation of the dynamics as in iterative Linear Quadratic Regulator (iLQR) in our description of DDP. The dropped second-order dynamics term can easily be added back in the derivations below. We refer readers to [3, 18] for a detailed overview of the vanilla DDP and iLQR algorithms.

The DDP algorithm consists of a forward pass and a backward pass. The forward pass simulates the dynamics forward in time obtaining a set of nominal state and control trajectories \((\tilde{x}_0:T, \tilde{u}_0:T-1)\), while the backward pass solves the Bellman equation with a 2nd order approximation of the costs and dynamics equations around the nominal trajectories. The boundary conditions for the value function \( V \) are obtained by performing a 2nd order Taylor expansion of the terminal cost \( \Phi \):

\[
V_{x,T} = \Phi_{xx}, \quad V_{x,T} = \Phi_x, \quad V_{T} = = 0. \tag{9}
\]

To derive the backward pass, we first perform a quadratic approximation of the cost function around \((\tilde{x}, \tilde{u})\)

\[
l(x, u) \approx l(\tilde{x}, \tilde{u}) + \left[ l_u \right]^T \delta u + \frac{1}{2} \left[ l_{xx} \right]^T \delta x + \left[ l_{xu} \right] \delta x + l_x \delta u,
\]

where \( \delta x := x - \tilde{x}, \delta u := u - \tilde{u} \). We also perform a linear approximation of the dynamics:

\[
f(x, u) \approx f(\tilde{x}, \tilde{u}) + f_x^T \delta x + f_u^T \delta u.
\]

Define \( Q := V'(f(x, u)) + l(x, u) \), with subscripts denoting partial derivatives. The next lemma describes the optimal policy and value function.

**Lemma 2.** The optimal policy for the approximated problem is Gaussian with mean \( \delta u^* \) and covariance \( \alpha Q_{uu}^{-1} \)

\[
\pi^*(\delta u|\delta x) = \mathcal{N}(\delta u; \delta u^*, \alpha Q_{uu}^{-1}) \tag{10}
\]

where the mean \( \delta u^* \) has the same form as in vanilla DDP

\[
\delta u^* = -Q_{uu}^{-1}(Q_{ux} \delta x + Q_u) = K \delta x + k. \tag{11}
\]

Consequently, the value function has the form

\[
V(x) = \tilde{V}(\tilde{x}) + V_H(\tilde{x}) + V_x(\tilde{x})^T \delta x + \frac{1}{2} \delta x^T V_{xx}(\tilde{x}) \delta x, \tag{12}
\]

The log-sum-exp is a smoothed combination of the local quadratic approximation and approaches \( \min_{\pi} \) as \( \alpha \to 0 \) when the problem reverts to the vanilla case.

We refer the readers to Appendix B in [17] for a proof of Lemma 2.

### IV. Multimodal Maximum Entropy DDP

While a unimodal Gaussian policy is able to achieve better exploration compared to the deterministic policy, it is often the case that multiple modes need to be explored simultaneously to converge to the global minimum [10]. In this section, we derive a multimodal extension to the ME-DDP introduced. Let \( \{\tilde{x}^{(n)}, \tilde{u}^{(n)}\}_{n=1}^N \) denote \( N \) different nominal state and control trajectories, and let \( \Phi^{(n)} \) corresponds to the respective quadratic approximation of \( \Phi \) around \( \tilde{x}^{(n)} \) and \( \tilde{u}^{(n)} \). Instead of using a single quadratic approximation of \( \Phi \) for the terminal cost as in (9), we use the combined approximation \( \tilde{\Phi} \)

\[
V_T(x) = \tilde{\Phi}(x) := -\alpha \ln \sum_{n=1}^N \exp \left( -\frac{1}{\alpha} \Phi^{(n)}(x) \right). \tag{17}
\]

The log-sum-exp is a smoothed combination of the local quadratic approximation and approaches \( \min_{\pi} \{\Phi^{(n)}\} \) as \( \alpha \to 0 \) as shown in Fig. 1.

The above equation becomes easier to work with when considering the exponential transform of the problem. Define \( \mathcal{E}_\alpha \) to be the following function

\[
\mathcal{E}_\alpha(y) := \exp \left( -\frac{1}{\alpha} y \right). \tag{18}
\]

We now define the reward \( r, R_T \) and desirability \( z \) as

\[
r_t := \mathcal{E}_\alpha(l_t), \quad r_T := \mathcal{E}_\alpha(\Phi), \quad z := \mathcal{E}_\alpha(V(x)). \tag{19}
\]
With this transformation, note that the desirability function \( z \) is exactly the partition function \( Z \) from (8) and is linear in both \( z' \) and \( r \) (denoting \( z' \) for the next timestep):

\[
\begin{align}
  z(x) &= Z(x) = \int z'(f(x, u)) r(x, u) \, du, \quad (20a) \\
  z_T(x_T) &= r(x_T).
\end{align}
\]

With this transformation, the optimal policy in (6) has the following elegant form

\[
\pi(u|x) = z(x)^{-1} z'(f(x, u)) r(x, u). \quad (21)
\]

Additionally, using the desirability function \( z \) to write (17), we see that \( z \) has an additive structure:

\[
z_T(x_T) = \sum_{n=1}^{N} z^{(n)}_{T}(x_T), \quad z^{(n)}_{T}(x_T) := r^{(n)}(x_T). \quad (22)
\]

The following lemma now shows that this structure holds for all time.

**Lemma 3.** Suppose that the terminal cost has the form (17). Then, for all \( t = 0, \ldots, T \), the desirability function \( z \) has the following additive structure

\[
z(x) = \sum_{n=1}^{N} z^{(n)}(x), \quad z^{(n)} := \int z^{(n)}(f(x, u)) r(x, u) \, du,
\]

**Proof.** This holds at the terminal time from (22). Suppose that \( z'(x) = \sum_{n=1}^{N} z^{(n)}(x) \). Substituting this in (20a), we get

\[
z(x) = \int \left( \sum_{n=1}^{N} z^{(n)}(f(x, u)) \right) r(x, u) \, du,
\]

\[
= \sum_{n=1}^{N} \int z^{(n)}(f(x, u)) r(x, u) \, du,
\]

\[
= \sum_{n=1}^{N} z^{(n)}(x).
\]

By induction, this holds for all time. \( \square \)

**Remark.** Note that the form of \( z^{(n)} \) is identical to the Bellman equation (20a). In other words, each \( z^{(n)} \) and \( V^{(n)} \) is computed exactly the same way as \( z \) and \( V \) in the unimodal case but with a different terminal condition \( \Phi^{(n)} \).

Substituting \( V \) back for \( z \) in (23) yields

\[
V(x) = -\alpha \ln \sum_{n=1}^{N} \exp \left( -\frac{1}{\alpha} V^{(n)}(x) \right). \quad (24)
\]

This result makes sense intuitively—the combined value function should be related to the minimum of the individual approximated value functions resulting from the different nominal states.

Fig. 1: Comparison of the individual quadratic approximation (top) and the log-sum-exp approximation (bottom) of the cost function \( l(x) \) with varying choices of inverse temperature \( \alpha \). Higher \( \alpha \) leads to smoother approximation.

Using the linearity of the desirability function (23), the optimal policy (21) has the form

\[
\pi(u|x) = z(x)^{-1} \left( \sum_{n=1}^{N} z^{(n)}(f(x, u)) \right) r(x, u),
\]

\[
= \sum_{n=1}^{N} \frac{z^{(n)}(x)}{z(x)} z^{(n)}(x)^{-1} z^{(n)}(f(x, u)) r(x, u),
\]

\[
= \sum_{n=1}^{N} w^{(n)}(x) \pi^{(n)}(u|x), \quad (25)
\]

where

\[
\pi^{(n)}(u|x) := z^{(n)}(x)^{-1} z^{(n)}(f(x, u)) r(x, u),
\]

\[
w^{(n)}(x) := z(x)^{-1} z^{(n)}(x), \quad \sum_{n=1}^{N} w^{(n)} = 1.
\]

This is exactly the policy obtained in the normal case, except that we consider \( z^{(n)} \) instead of \( z \). Since \( V^{(n)} \) is quadratic in the state, each \( \pi^{(n)} \) will be Gaussian as before:

\[
\pi^{(n)}(\delta u^{(n)} | \delta x^{(n)}) = N(\delta u^{(n)}; \delta u^{(n)} \star, \alpha(Q^{(n)} - I)^{-1}) \quad (26)
\]

where \( \delta x^{(n)} = x - \bar{x}^{(n)} \) and \( \delta u^{(n)} = u - \bar{u}^{(n)} \) are now evaluated relative to the nominal trajectories for corresponding to the \( n \)th approximation, with \( \delta u^{(n)} \star \) defined analogous to (11) but using the approximations around \( (\bar{x}^{(n)}, \bar{u}^{(n)}) \).

Importantly, form of (25), we see that \( \pi \) is a mixture of Gaussians with component weights \( w^{(n)} \) computed using the quadratic approximation of the value function (12) and are adaptive to disturbances. We refer the readers to Appendix C in [17] for more details.

Since both \( z \) and \( \pi \) are weighted sums of \( z^{(n)} \) and \( \pi^{(n)} \), computing the solution to the backward pass of MME-DDP is equivalent to solving for ME-DDP around the \( N \) different nominal trajectories and then composing the value functions and policies using (24) and (25).
Algorithm 1: Backward Pass
1. Compute $V(T), V_x(T)$ and $V_{xx}(T)$ using $\Phi$
2. for $t = T - 1$ to 0 do
   3. Compute $I, Q$ and their derivatives for timesteps $t$
   4. Regularize $Q_{uu}$ to be PD
   5. Compute $K_t, K_x, V_x(t - 1), V_{xx}(t - 1)$ as in Vanilla DDP
   6. $\Sigma_t \leftarrow \alpha Q_{uu}^{-1}$
   7. $V_H \leftarrow V_H + \frac{\alpha}{2}(\ln|Q_{uu}| - n_{\alpha}(2\pi\alpha))$

A. Compositionality and Linear Solvable Optimal Control

A key component of our work is the compositionality of policies—solving for the full policy $\pi$ by solving for the individual policies $\pi^{(n)}$ then combining them via (25). In [19], the KL Divergence regularized control is considered and the compositionality of controllers is introduced by exploiting the linearity of the exponential value function and the optimal policy. Unlike [19], we allows the running cost $I(x, u)$ to be an arbitrary function of the controls $u$. Furthermore, we provide practical algorithms in the form of ME-DDP and MME-DDP. Similarly, in the field of RL [20], compositionality has been used on maximum entropy optimal policies to solve a conjunction of tasks by combining maximum entropy policies which solve each of the tasks individually.

Unlike the above works, the approach our work takes focuses on the topic of exploration rather than compositionality. Our work is most similar to [10], which shows that the multimodal exploration is able to outperform similar methods which only consider unimodal exploration policies. However, we make use of compositionality and solve for the value function explicitly using DDP which allows for the policy to be recomputed online in realtime.

B. Exploration and Control-as-Inference

Our work is related to the Control-as-Inference framework [14, 21, 22, 23], where finding the optimal policy is posed as an inference problem by minimizing the KL divergence, with maximum entropy emerging as a special case of this when the prior is uniform. This framework provides a natural exploration strategy based on entropy maximization. Since the optimal policy is usually intractable, approaches in this area approximate the optimal policy distribution using either neural networks or by using tractable surrogates such as Gaussian distributions. Our work can be viewed as an extension to the latter approach by considering mixtures of Gaussians instead of unimodal Gaussians.

Our work has similar flavors to SaDDP in [24] as both methods rely on DDP and incorporate sampling. In their case, sampling is leveraged to address the problem of discontinuity and bypass the use of analytical derivatives, whereas sampling is used in this work to explore multiple modes simultaneously.

Algorithm 2: (Unimodal) Maximum Entropy DDP
1. Initialize $x^{(1:2)}, u^{(1:2)}, K^{(1:2)}, \Sigma^{(1:2)}$
2. for $i = 1$ to $I$ do
   3. if $i \% m = 0$ then
      4. $x^{(1)}, u^{(1)}, K^{(1)} \leftarrow$ lowest code mode
      5. $x^{(2)}, u^{(2)}, K^{(2)} \sim \pi^{(1)}$
   6. for $n = 1$ to 2 in parallel do
      7. $x^{(n)} \leftarrow$ Rollout dynamics
      8. $k^{(n)}, \Sigma^{(n)}, V_H^{(n)} \leftarrow$ Backward Pass
      9. $x^{(n)}, u^{(n)}, J^{(n)} \leftarrow$ Line Search

VI. CONNECTIONS TO EXISTING WORKS

Algorithm 3: Multimodal Maximum Entropy DDP
1. Initialize $x^{(1:N)}, u^{(1:N)}, K^{(1:N)}, \Sigma^{(1:N)}, \pi$
2. for $i = 1$ to $I$ do
   3. if $i \% m = 0$ then
      4. $x^{(1)}, u^{(1)}, K^{(1)} \leftarrow$ lowest code mode
      5. $x^{(2:N)}, u^{(2:N)}, K^{(2:N)} \sim$ GMM $\pi$ with weights $w^{(2:N)}$
   6. for $n = 1$ to $N$ in parallel do
      7. $x^{(n)} \leftarrow$ Rollout dynamics
      8. $k^{(n)}, \Sigma^{(n)}, V_H^{(n)} \leftarrow$ Backward Pass
      9. $x^{(n)}, u^{(n)}, J^{(n)} \leftarrow$ Line Search
     10. Compute $w^{(n)}$ using $J^{(n)}$ and $V_H^{(n)}$

VI. ALGORITHMS

There are three main algorithmic issues that need to be addressed when implementing ME-DDP and MME-DDP.

Forward Pass: The derivation in earlier sections only describes how to perform the backward pass of DDP to compute the optimal Gaussian mixture policy (25), leaving the question of how to apply the new stochastic policy for the forward pass unanswered.

For ME-DDP, we perform multiple realizations of the stochastic policy at each timestep. Taking $N$ realizations for each of the $T$ timesteps will result in polynomial growth $O(T^N)$ of required samples. Instead, we sample the entire feedforward controls from the stochastic policy at $t = 0$ and then apply the deterministic feedback policy for times $t = 1$ to $T - 1$. To handle the added multi-modality of the optimal MME-DDP policy, we sample from a categorical distribution to determine which of the $N$ modes will be used for the control of a particular sample trajectory, and then sample the feedforward controls as in the ME-DDP case.

Convergence: With a stochastic policy, the cost of the trajectory after sampling may be higher in cost than the original trajectory or even unbounded. To guarantee the convergence of the algorithms, we draw inspirations from [25] and apply the mean deterministic controls from the mode with the smallest cost to at least one sampled trajectory. This guarantees that the minimum cost over all $N$ samples
TABLE I: Comparison of the mean and standard deviations of the cost for vanilla DDP, ME-DDP and MME-DDP, computed on 16 different DDP runs. The best mean cost for each system is boldfaced. Positive values of mean reduction correspond to a reduction. Significant reduction in mean and standard deviation can be observed from MME over both ME and vanilla DDP.

| System          | Vanilla Mean | Std | ME Mean | Std | MME Mean | Std | MME vs Vanilla ΔMean% | MME vs ME ΔMean% |
|-----------------|--------------|-----|---------|-----|----------|-----|-----------------------|------------------|
| 2D Point Mass   | 32.25        | 0.00| 10.76   | 9.55| 1.76     | 0.00| 94.55                 | 83.69            |
| Car             | 5.31         | 0.00| 4.99    | 0.64| 3.76     | 0.87| 29.16                 | 24.63            |
| Quadcopter      | 0.98         | 0.00| 0.90    | 0.18| 0.54     | 0.02| 45.08                 | 40.25            |
| Manipulator     | 22.84        | 0.00| 20.28   | 4.68| 12.56    | 3.68| 45.00                 | 38.06            |

Fig. 2: Task setup for the manipulator. The goal is to reach the red block past the obstacles while avoiding collisions. is monotonically decreasing, preserving the convergence properties of DDP:

**Lemma 4.** Each iterate of ME-DDP and MME-DDP results in a cost that is no worse than vanilla DDP given the current best nominal control is identical.

We refer the readers to Appendix D in [17] for the proof.

**Frequency of Sampling:** Since the weights \( w^{(n)} \) for each mode for ME-DDP are proportional to the value function \( Z^{(n)} \), modes which have high cost are unlikely to be resampled in the next iteration of the forward pass even if they will converge to a more optimal local minimum given enough DDP iterations. To alleviate this issue, we only resample the controls for each mode after every \( m \) iterations, increasing the probability of jumping out of suboptimal local minima.

The full ME-DDP and MME-DDP algorithms are presented in Algorithm 2 and Algorithm 3, along with their backward pass in Algorithm 1, where variables without indices denote the entire trajectory, \( x^{(n)} \) denotes \( x_{0:T}^{(n)} \). In short, both algorithms consist of keeping the lowest cost sample and sampling the rest from the stochastic policy \( \pi \) every \( m \) iterations for the forward pass, then running the backward pass for each sample. Both passes can be executed in parallel for each sample.

**VII. Simulations**

In this section, we compare the performance of the proposed MME-DDP algorithm against the ME-DDP and vanilla DDP algorithms on four systems: 2D Point Mass, 2D Car, Quadcopter and Manipulator. Obstacle avoidance is implemented as a soft-constraint with \( h_{\text{obs}} = \exp \left( -\frac{d_{\text{obs}}^2}{2r_{\text{obs}}^2} \right) \), where \( d_{\text{obs}} \) and \( r_{\text{obs}} \) are the distance and radius of the obstacle respectively. The controls are zero-initialized for all systems. For the resampling frequency, we set \( m = 8 \). Table II compares the mean and standard deviation of the solver times on the 2D Car problem for DDP and MME-DDP with 8 modes on a Ryzen 9 3950X processor.

**A. 2D Point Mass**

We first test the algorithms on an illustrative 2D point-mass double integrator reaching task while avoiding obstacles in a maze-like environment. Both the top and middle paths are suboptimal local minima as they are blocked by obstacles, with the top path having an obstacle near the end of the path. The results are shown in the first row of Fig. 3.

**B. 2D Car**

We next test on a 2D Car with dynamics of Dubin’s vehicle under jerk control. The task here is again a reaching task while avoiding two circular obstacles. A suboptimal local minimum exists in the middle which goes in between both obstacles. The results are shown in the second row of Fig. 3.

**C. Quadcopter**

We test on a 3D quadcopter with states \( x = [p_x, p_y, p_z, \Psi, \theta, \phi, v_x, v_y, v_z, \tau, \tau_x, \tau_y, \tau_z]^T \in \mathbb{R}^{12} \) and controls \( u = [f_t, \tau_x, \tau_y, \tau_z]^T \in \mathbb{R}^{4} \). We refer readers to [26] for a full description of the dynamics. The task is to reach a target on the other side of four spherical obstacles set up in a square pattern. A suboptimal local minima is present in the intersection of all four obstacles in the center which only MME-DDP is able to consistently escape from, as shown in the third row of Fig. 3.

**D. Manipulator**

Finally, we test on a torque-controlled 7-DOF manipulator based off a simplified version of the Franka EMIKA Panda arm. The task here is for the end effector to reach the goal position without colliding with obstacles (see Fig. 2). Cylindrical obstacles are placed between the starting position and the end effector, creating multiple suboptimal local minima in the cost landscape. Again, only MME-DDP is able to consistently reach the target without intersecting any of the obstacles, as shown in the bottom row of Fig. 3.

**Performance Comparison:** Comparing the three algorithms, we observe that in the case of one global minimum
Fig. 3: (a)–(c) Position trajectories for the 2D point mass, car, quadcopter and manipulator systems from 16 different DDP runs. For the manipulator, the projections of the end effector trajectories on the XY-plane are plotted. (d) Convergence plots for all three algorithms. The solid line denotes the mean, the dark shaded region represents the $2\sigma$ relative uncertainty, while the dotted lines denote the minimum and maximum costs. In all examples, MME-DDP is able converge to a better global minimum due to having better exploration.

(Point Mass and Manipulator), vanilla DDP gets stuck in a local minimum. Unimodal ME-DDP explores several minima but lacks the capability to explore each sufficiently. In contrast, the additional exploration capability helps MME-DDP find the best minimum. In the case of many minima of similar cost (Car and Quadcopter), vanilla and ME-DDP get stuck in one or few suboptimal minima while MME-DDP explores several minima simultaneously. As obstacles are implemented as soft constraints, the shaded region around obstacles in Fig. 3 only provides a visualization and is not the obstacle boundary. We also present a comparison of convergence for each algorithm in Table I and Fig. 3d. Across all tasks, it is clear that both ME-DDP and MME-DDP are able to achieve a lower mean cost than vanilla DDP due to converging to a more optimal local minimum. Furthermore, MME-DDP is able to consistently achieve a significantly lower cost, highlighting the advantages of multimodal exploration.

VIII. CONCLUSION

In this paper, we derived ME-DDP and MME-DDP, two algorithms based off the maximum entropy formulation of DDP which provide improved exploration capabilities over the vanilla algorithm. Our results suggest that the added stochasticity and multimodal exploration improves the ability of DDP to escape from suboptimal local minima in environments with multiple local minima.

Future work include hardware implementation to verify the exploration benefits of the proposed algorithms. On the theoretical side we will investigate the conditions and rate of convergence, as well as generalizations that include the stochastic, risk sensitive and model predictive control cases.

APPENDIX A

PROOF OF LEMMA 1

We first restate Lemma 1 for the convenience of the reader.

**Lemma 1.** The optimal policy \( \pi^* \) solving the infimum in (5) is the Gibbs distribution

\[
\pi^*(u|x) = Z^{-1} \exp \left( -\frac{1}{\alpha} \left[ V'(f(x,u)) + l(x,u) \right] \right),
\]

where \( Z \) denotes the partition function

\[
Z(x) = \int \exp \left( -\frac{1}{\alpha} \left[ V'(f(x,u)) + l(x,u) \right] \right) du.
\]

Consequently, the value function \( V \) takes the form

\[
V(x) = -\alpha \ln Z(x).
\]

**Proof.** From the Bellman equation (5), \( \pi^* \) is the solution to the following constrained optimization problem

\[
\inf_{\pi} \mathbb{E}_{u \sim \pi} [l(x,u) + V'(f(x,u))] - \alpha H[\pi(\cdot|x)] du
\]

s.t. \( \int \pi(u|x) du = 1 \) \hspace{1cm} (A.1)

To solve this, we first formulate the Lagrangian \( \mathcal{L} \) as

\[
\mathcal{L} = \mathbb{E}_{u \sim \pi} [l(x,u) + V'(f(x,u))] - \alpha H[\pi(\cdot|x)] + \lambda \left( 1 - \int \pi(u|x) du \right) \hspace{1cm} (A.3)
\]

\[
= \int_{\mathbb{R}^n} \pi(u|x) \left( Q(x,u) + \alpha \ln \pi(u|x) - \lambda \right) du + \lambda
\]

where we have defined \( Q(x,u) := l(x,u) + V'(f(x,u)) \) for simplicity. Applying first-order optimality conditions then gives

\[
0 = l(x,u) + V'(f(x,u)) + \alpha \left( 1 + \ln \pi^*(u|x) \right) - 1
\]

\[
\Rightarrow \pi^*(u|x) = \exp \left( -\frac{1}{\alpha} \left[ l(x,u) + V'(f(x,u)) - 1 \right] \right)
\]

Using the constraint on the integral of \( \pi^* \) then gives us

\[
1 = \int \pi^*(u|x) = \int \exp \left( -\frac{1}{\alpha} Q(x,u) \right) \exp \left( \frac{1}{\alpha} \lambda - 1 \right) du
\]

\[
\Rightarrow \exp \left( \frac{1}{\alpha} \lambda - 1 \right) = \left( \int \exp \left( -\frac{1}{\alpha} Q(x,u) \right) du \right)^{-1}
\]

\[
= Z(x)^{-1}, \quad Z(x) := \int \exp \left( -\frac{1}{\alpha} Q(x,u) \right) du
\]

Hence, the optimal policy \( \pi^* \) is of the form

\[
\pi^*(u|x) = Z(x)^{-1} \exp \left( -\frac{1}{\alpha} \left[ l(x,u) + V'(f(x,u)) \right] \right) du
\]

Finally, to solve for the value function \( V \) in (5), we plug in the optimal policy \( \pi^* \) (A.10) to obtain

\[
V(x) = \int \pi^*(u|x) \left( Q(x,u) + \alpha \ln \pi^*(u|x) \right) du
\]

\[
= \int \pi^*(u|x) \left( Q(x,u) - \alpha \ln Z(x) - Q(x,u) \right) du
\]

\[
= -\alpha \ln Z(x) \int \pi^*(u|x) du
\]

\[
= -\alpha \ln Z(x)
\]

\( \square \)
APPENDIX B
PROOF OF LEMMA 2

We start by restating Lemma 2 for the benefit of the reader.

**Lemma 2.** The optimal policy for the approximated problem is Gaussian with mean \( \delta u^* \) and covariance \( \alpha Q_{uu}^{-1} \)

\[
\pi^*(\delta u|\delta x) = \mathcal{N}(u; \delta u^*, \alpha Q_{uu}^{-1})
\]

where the mean \( \delta u^* \) has the same form as in vanilla DDP

\[
\delta u^* = -Q_{uu}^{-1}\left(Q_{ux}\delta x + Q_u\right) = K\delta x + k.
\]

Consequently, the value function has the form

\[
V(x) = \bar{V}(x) + V_H(\bar{x}) + V_x(\bar{x})^T\delta x + \frac{1}{2}\delta x^T V_{xx}(\bar{x})\delta x,
\]

where

\[
\bar{V}(\bar{x}) = V'(\bar{x}) + l(\bar{x}, \bar{u}) - \frac{1}{2}Q_{uu}^{-1}Q_{uu}Q_u,
\]

\[
V_H(\bar{x}) = \frac{1}{2}\left(\ln|Q_{uu}| - n_u \ln(2\pi\alpha)\right),
\]

\[
V_x(\bar{x}) = Q_x + K^T Q_{uu}k + K^T Q_u + Q_{ux}^T k.
\]

\[
V_{xx}(\bar{x}) = Q_{xx} + K^T Q_{uu} K + K^T Q_{ux} + Q_{ux}^T K.
\]

**Proof.** We start by performing a Taylor expansion of \( Q \) with respect to \( x \) and \( u \) to obtain

\[
\delta Q := \begin{bmatrix} Q_u \\ Q_u^T \end{bmatrix} \begin{bmatrix} \delta x \\ \delta u \end{bmatrix} + \frac{1}{2} \begin{bmatrix} \delta x \\ \delta u \end{bmatrix}^T \begin{bmatrix} Q_{xx} & Q_{xu} \\ Q_{ux} & Q_{uu} \end{bmatrix} \begin{bmatrix} \delta x \\ \delta u \end{bmatrix}.
\]

Expanding \( \delta Q \) from \( \text{(B.2)} \), collecting terms and completing the square yields

\[
\delta Q = \begin{bmatrix} Q_u + Q_{xu} \delta x \\ \frac{1}{2} \delta u^T Q_{uu} \end{bmatrix}^T \begin{bmatrix} \delta x \\ \delta u \end{bmatrix} + \begin{bmatrix} Q_x \delta x + \frac{1}{2} \delta x^T Q_{xx} \delta x \\ \frac{1}{2} \delta u^T Q_{uu} \delta u \end{bmatrix}
\]

\[
= \frac{1}{2} (\delta u - \delta u^*)^T Q_{uu} (\delta u - \delta u^*) - \frac{1}{2} \delta u^T Q_{uu} \delta u^* + \left( Q_x \delta x + \frac{1}{2} \delta x^T Q_{xx} \delta x \right)
\]

where \( \delta u^* \) is defined as

\[
\delta u^* := -Q_{uu}^{-1}(Q_{ux}\delta x + Q_u) = K\delta x + k.
\]

Plugging the above into \( \text{(6)} \) then yields

\[
\pi^*(u|x) \propto \exp\left(-\frac{1}{\alpha} (\delta u - \delta u^*)^T Q_{uu} (\delta u - \delta u^*)\right),
\]

\[
= \exp\left(-\frac{1}{\alpha} (\delta u - \delta u^*)^T \Sigma^{-1}(\delta u - \delta u^*)\right), \quad \Sigma := \alpha Q_{uu}^{-1},
\]

which is the pdf of a multivariate Gaussian distribution with mean \( \delta u^* \) and covariance \( \alpha Q_{uu}^{-1} \).

Finally, to compute the value function, we first compute \( Z \):

\[
Z(x) = \int \exp\left(-\frac{1}{\alpha} [Q(x,u)]\right) du
\]

\[
= \exp\left(-\frac{1}{\alpha} \left[ V'(f(\bar{x}, \bar{u})) + l(\bar{x}, \bar{u}) + Q_x \delta x + \frac{1}{2} \delta x^T Q_{xx} \delta x - \frac{1}{2} (\delta u - \delta u^*)^T \Sigma^{-1} (\delta u - \delta u^*) \right]\right)
\]

\[
= \exp\left(-\frac{1}{\alpha} \bar{V}(x)\right) (2\pi)^{-n_u} |\alpha Q_{uu}^{-1}|^{\frac{1}{2}}
\]
where $\hat{V}$ contains all the terms that corresponds to the case of vanilla DDP. Note that

$$-\alpha \ln \left[ \left(2\pi|Q_{uu}^{-1}|\right)^{\frac{1}{2}} \right] = -\frac{\alpha}{2} \left( \ln(2\pi\alpha) + \ln|Q_{uu}^{-1}| \right) \quad (B.11)$$

$$= \frac{\alpha}{2} \left( \ln|Q_{uu}| - n_u \ln(2\pi\alpha) \right) \quad (B.12)$$

$$:= V_H(\bar{x}) \quad (B.13)$$

Consequently, applying (8) yields

$$V(x) = \hat{V}(x) - \frac{\alpha}{2} \ln \left(2\pi|Q_{uu}^{-1}|\right) \quad (B.14)$$

$$= \hat{V}(x) + V_H(\bar{x}) + V_x(\bar{x})^T \delta x + \frac{1}{2} \delta x^T V_{xx}(\bar{x}) \delta x, \quad (B.15)$$

where

$$\hat{V}(\bar{x}) = \hat{V}'(\bar{x}) + l(\bar{x}, \tilde{u}) - \frac{1}{2} k^T Q_{uu} k, \quad (B.16)$$

$$= \hat{V}'(\bar{x}) + l(\bar{x}, \tilde{u}) - \frac{1}{2} Q_u^T Q_{uu}^{-1} Q_u, \quad (B.17)$$

$$V_H(\bar{x}) = \frac{\alpha}{2} \left( \ln|Q_{uu}| - n_u \ln(2\pi\alpha) \right), \quad (B.18)$$

$$V_x(\bar{x}) = Q_x + K^T Q_{uu} k + K^T Q_u + Q_{ux}^T, \quad (B.19)$$

$$= Q_x - Q_{uu} Q_{uu}^{-1} Q_u, \quad (B.20)$$

$$V_{xx}(\bar{x}) = Q_{xx} + K^T Q_{uu} K + K^T Q_{ux} + Q_{ux}^T K, \quad (B.21)$$

$$= Q_{xx} - Q_{uu} Q_{uu}^{-1} Q_{ux}. \quad (B.22)$$

$\square$
Appendix C

Further Details on MME-DDP

From (25), the optimal policy for ME-DDP is a mixture distribution of Gaussians

\[ \pi(u|x) = \sum_{n=1}^{N} w^{(n)}(t,x) \pi^{(n)}(u|x) \]  

(C.1)

where

\[ \pi^{(n)}(\delta u^{(n)}|\delta x^{(n)}) = N\left(\delta u^{(n)}; \delta u^{(n)\ast}, \alpha(Q^{(n)}_{uu})^{-1}\right) \]  

(C.2)

\[ w^{(n)}(t,x_t) := z_t(t,x_t)^{-1} z_t^{(n)}(t,x) \]

(C.3)

\[ V^{(n)}(t,x_t) = \bar{V}^{(n)}(t,\bar{x}^{(n)}) + V_H^{(n)}(t,\bar{x}^{(n)}) + V_x^{(n)}(t,\bar{x}^{(n)})^T \delta x^{(n)} + \frac{1}{2} \delta x^{(n)^T} V_{xx}^{(n)}(t,\bar{x}^{(n)}) \delta x^{(n)} \]  

(C.4)

where we have included time indices to emphasize in \( w^{(n)} \) and \( V^{(n)} \) to emphasize that these variables are both time and state dependent. Assuming that the algorithm has converged, we should have \( V_x^{(n)} \approx 0 \). Consequently, each value function \( V^{(n)} \) will be centered around the nominal trajectory \( \bar{x}^{(n)} \) and serve as a “distance metric” weighted by the nominal cost \( \bar{V}^{(n)} \) of the trajectory. Hence, when a disturbance occurs, the weights \( w^{(n)} \) of the mixture distribution \( \pi \) in (C.1) will adapt to reflect the new best mode based on the existing quadratic approximations of each value function.
Lemma 5. Each iterate of ME-DDP and MME-DDP results in a cost that is no worse than vanilla DDP given the current best nominal control is identical.

Proof. Let \( \bar{u} \) denote the current nominal control and let \( u^{\text{DDP}} \) denote the next control iterate from vanilla DDP.

We first show that this holds for ME-DDP. Let \( \bar{u}^{(1)}, \bar{u}^{(2)} \) denote the current nominal control trajectories for ME-DDP, with

\[
\bar{u}^{(1)} = \bar{u}, \quad J(\bar{u}^{(1)}) \leq J(\bar{u}^{(2)}) \tag{D.1}
\]

As noted in the remark for Lemma 2, the update rule for ME-DDP are exactly the same as in vanilla DDP, with the mean control of \( \pi^* \) matching that of vanilla DDP. Let \( \hat{u}^{(1)} \) and \( \hat{u}^{(2)} \) denote the updated means after one step of ME-DDP, such that

\[
u^{(1)} \leftarrow u^{(i)}, \quad i = \arg \min_{i \in \{1, 2\}} J(\hat{u}^{(i)}) \tag{D.2}
\]

\[
u^{(2)} \sim \mathcal{N}(u^{(j)}; \Sigma^{(j)}), \quad j = \arg \max_{j \in \{1, 2\}} J(u^{(j)}) \tag{D.3}
\]

Consequently, we must have that

\[
\min\{J(u^{(1)}), J(u^{(2)})\} = J(u^{(1)}) \leq J(\hat{u}^{(1)}) = J(u^{\text{DDP}}) \tag{D.4}
\]

This same can similarly be shown for MME-DDP assuming that \( \bar{u}^{(1)} = \bar{u} \):

\[
\min\{J(u^{(1)}), \ldots, J(u^{(N)})\} = J(u^{(1)}) \leq J(\hat{u}^{(1)}) = J(u^{\text{DDP}}) \tag{D.5}
\]
