Polycomb repressive complexes are evolutionarily conserved complexes that maintain transcriptional repression during development and differentiation to establish and preserve cell identity. We recently described the fundamental role of PRC1 in preserving intestinal stem cell identity through the inhibition of non–lineage-specific transcription factors. To further elucidate the role of PRC1 in adult stem cell maintenance, we now investigated its role in LGR5\(^5\) hair follicle stem cells during regeneration. We show that PRC1 depletion severely affects hair regeneration and, different from intestinal stem cells, derepression of its targets induces the ectopic activation of an epidermal–specific program. Our data support a general role of PRC1 in preserving stem cell identity that is shared between different compartments. However, the final outcome of the ectopic activation of non–lineage-specific transcription factors observed upon loss of PRC1 is largely context-dependent and likely related to the transcription factors repertoire and specific epigenetic landscape of different cellular compartments.

INTRODUCTION

Cellular identity is preserved by different layers of transcriptional control. Among the factors and molecular circuits involved in establishing and maintaining cell type–specific transcriptional profiles, epigenetic regulators play a pivotal role. Alterations in these mechanisms are one of the leading causes of different pathologies, such as cancer (1, 2). Polycomb group (PcG) proteins are a class of evolutionarily conserved molecules required to maintain transcriptional repression during development and differentiation (3). PcG proteins assemble into two major complexes named Polycomb repressive complex 2 (PRC2) and PRC1. PRC1 and PRC2 share the vast majority of their targets, characterized by CpG-rich regions at promoters, where they are recruited sequentially. The core of PRC2 is composed of the mutually exclusive catalytic subunits EZH1 and EZH2, which deposit the mono-, di-, and trimethylation on lysine 27 of histone H3 (H3K27me3), and of two structural proteins SUZ12 and EED, which are necessary for complex formation and stabilization (4, 5). PRC1 is responsible for the deposition of a single ubiquitin moiety on lysine 119 of histone H2A (H2AK119Ub1) through the catalytic subunits RING1A or RING1B. In addition, it has been described that PRC1 exists in several different forms characterized by the presence of different mutually exclusive Polycomb group ring finger (PCGF) proteins (6). These different complexes have been defined as “canonical” or “noncanonical” depending on their ability to associate with chromobox (CBX) proteins. While CBX-containing canonical PRC1 complexes are tethered to chromatin by PRC2–dependent deposition of H3K27me3, the recruitment of noncanonical complexes remains independent of PRC2 activity.

The activity and biological function of PRC1 and PRC2 has been intensively investigated in the past 20 years during embryonic development and using embryonic stem cells (ESCs) (3, 5), while their role in adult stem cells and tissue homeostasis has only recently attracted attention (7–14). Adult tissues are constantly regenerated and maintained by a pool of stem cells, which are able to compensate for cell loss and tissue damage while preserving stem cell pools (15). We recently uncovered the central role of PRC1 activity in preserving intestinal stem cell (ISC) identity through the transcriptional repression of non–lineage-specific transcription factors (TFs), which are able to interfere with the transcriptional program stimulated by the Wnt pathway required for the maintenance of the ISC pool (9). With the aim to uncover whether this is a general PcG role in adult stem cells, we now investigated the consequences of PRC1 loss of activity in a stem cell compartment from a different tissue with a distinct developmental origin—hair follicle stem cells (HFSCs).

The skin is the largest organ of the body. It is the first barrier against external insults such as bacteria and virus infections, toxic agents, and ultraviolet radiation, preserving, at the same time, water and temperature homeostasis. In mammals, the epidermis comprises the interfollicular epidermis and the pilosebaceous unit composed of the hair follicle (HF) and the sebaceous gland. During morphogenesis, which begins after delivery, HFs grow downward in the dermal compartment of the skin from the hair bulge and its associated germ (16). Hair regeneration is fueled by two different stem cell pools located in the bulge and hair germ. The bulge contains both CD34\(^+\) and LGR5\(^5\) (Leucine Rich Repeat Containing G Protein–coupled-receptor-5) stem cells, while the hair germ is exclusively colonized by LGR5\(^5\) stem cells (17, 18). Throughout life, HFs cycle between proliferation (anagen), destruction (catagen), and resting (telogen) phases (19). Anagen onset is activated when WNT proliferative signals overcome a bone morphogenetic protein threshold (20, 21), and LGR5\(^5\) HFSCs are essential during anagen to sustain HF growth (22). These cells first proliferate to form multipotent progenitors that briefly divide and give rise to matrix cells that will generate all the inner layers of the differentiating

HF (23, 24). During anagen progression, LGR5+ stem cells expand downward to constitute the outer root sheet (ORS) that delimitates the follicle. During anagen phase, LGR5+ HFSCs appear to be functionally similar to LGR5+ ISCs, being actively proliferating stem cells supporting a renewing tissue. For these reasons, they represent a good system to uncover general, stem cell–specific PRC1 activities.

Here, we report that the activity of PRC1 is essential to sustain LGR5+ HFSC and general HF regeneration. We further characterized the direct molecular circuits triggered by PRC1 loss of function and found that, despite the fact that a large part of PRC1 activity is associated with active gene expression, the phenotypic outcome of its loss of function can be primarily ascribed to its canonical repressive functions.

In this context, PRC1 is directly involved in suppressing an epidermal transcriptional program maintaining silencing of the master epidermal regulator Ascl2. Taking advantage of parallel data generated in ISCs, we further show that, despite the fact that PRC1 retains a general role in suppressing developmental programs across tissue and stem cell compartments, the molecular phenotypes triggered by PRC1 loss of function are strongly dependent on the cellular context, and therefore, by the repertoire of the expressed TFs in any given cell.

RESULTS

PRC1-dependent H2AK119Ub1 is required for HF regeneration

To uncover the general mechanisms by which PRC1 activity contributes to lineage identity in different adult stem cell populations, we took advantage of the LGR5-GFP-ires-CreERT2/Ring1a−/−/Ring1b fl/fl/Rosa26lox-stop-lox LacZ compound model (hereof Ring1a/b ctrl mice) that we have previously generated (Fig. S1A) (9). The Lgr5 transgene is homogenously expressed in a population of actively cycling and long-lived HFSCs that, from the base of the hair bulb, gradually expand through the ORS, contributing to the regeneration of the follicle (18). We used this genetic model to acutely abrogate PRC1 activity in 8 to 12 weeks, sex-matched mice and showed that four daily tamoxifen injections are sufficient to abolish PRC1 activity in LGR5+ [green fluorescent protein–positive (GFP+)] HFSCs, as shown by the loss of H2AK119Ub1 in GFP+ cells of telogen HFs (Fig. 1, A and B).

HF regeneration in adult mice is a critical mechanism through which fur is maintained during the entire life span. HFs cycle synchronously during the first 10 to 11 weeks of age and then gradually lose synchrony, despite maintaining the same regenerating capabilities (fig. S1B) (18, 19, 25). To investigate the role of PRC1 in adult HFSCs during HF regeneration, we exploited the possibility to resynchronize HFs by means of follicles plucking. As soon as the hair is removed, follicles rapidly and synchronously enter into anagen phase and start to cycle (25). To abrogate PRC1 activity from the first phases of HF regeneration, we administered tamoxifen in adult mice 1 day before waxing the back skin (Fig. 1C). After 12 days from waxing, while the fur of Ring1a/b ctrl mice was completely regenerated (Fig. 1D, top), we severely delayed follicle regeneration in Ring1a/b dKO mice in the absence of PRC1 activity (Fig. 1D, bottom). We further confirmed this result by lineage-tracing analyses, taking advantage of a Rosa26lox-stop-lox LacZ allele to follow LACZ expression in the progeny of LGR5+ stem cells. Twelve days after waxing, we markedly reduced the number of β-galactosidase (β-Gal)–expressing HFs in Ring1a/b dKO animals, suggesting that the residual hair growth is derived from wild-type HFs (Fig. 1E).

Conserved PRC1-repressed transcriptional programs are required to preserve HFSCs and ISCs

Our results suggest that the loss of PRC1 induces similar phenotypic outcomes in HFSCs compared to our previous results with ISCs (9). Whether this involves common or cell type–specific pathways remains an important open question. To investigate the transcriptional changes induced by PRC1 loss of function in anagen-activated LGR5+ stem cells, we collected the skin of Ring1a/b dKO and ctrl adult mice 8 days from waxing (Fig. 3A). HFs were isolated and reduced at single cells, and LGR5+ cells were isolated by fluorescence-activated cell sorting (FACS) to perform RNA sequencing (RNA-seq) analyses. FACS analysis on the same cells stained for H2AK119Ub1 demonstrated that tamoxifen treatment results in >70% loss of PRC1 activity in LGR5+ (GFP+) cells (Fig. 3B). RNA-seq analysis in these cell populations revealed a >5-fold bias in genes up-regulation (1066 up-regulated versus 187 down-regulated genes) that is consistent with the general PRC1 role as transcriptional repressor also in the HF compartment (Fig. 3C). Gene ontology (GO) analysis on differentially expressed genes showed that up-regulated genes are primarily associated with general developmental processes (Fig. 3D). In contrast, down-regulated genes were specifically enriched by factors involved in HF morphogenesis, HFSC maintenance, and hair cycle progression (Fig. 3E), such as Sonic hedgehog (23, 27). Moreover,
functional annotation revealed that DNA binding TFs, and particularly homeotic TFs, were overrepresented among the genes upregulated in Ring1a/b dKO (fig. S3A). The additional comparison in respect to transcriptional data obtained from several tissues (ENCODE; fig. S3B, bottom) highlighted that the loss of PRC1 activity results in the transcriptional activation of non–lineage-specific genes that are preferentially expressed in distinct tissue compartments. In contrast, down-regulated genes were primarily expressed in activated LGR5+ HFSCs (fig. S3B, top), further corroborating impaired activation of HFSC regenerative capabilities in the absence of PRC1 activity. These data are in agreement with our previous finding in ISCs (9), further highlighting the conserved essential role of PRC1 in maintaining lineage identity within adult tissues. Whether this involves common or specific mechanisms remains an open question. Thus, we searched for common classes of genes that could be potentially involved with the loss of cell identity in ISCs versus HFSCs upon PRC1 inactivation. We compared RNA-seq profiles in both stem cell compartments and found that none of the down-regulated genes were in common in accordance with the distinct identity of the two stem cell populations (fig. S3C). In contrast, we found approximately one-fourth of the up-regulated genes (255 genes, ≈25%) in common between ISC and HFSC (fig. S3D). This group of genes was enriched by mainly homeobox-containing TFs involved in regulating general developmental processes (fig. S3E). Several ZIC (Zinc finger protein of the cerebellum) TFs (Zic1, Zic4, and Zic5; fig. S3F), as well as Sox7, Hoxa10, and Hoxb13 (fig. S3G), were present within this list. Together, these data suggest that

PRC1 plays a common general role in distinct stem cell compartments to prevent activation of non–lineage-specific, homeobox-containing TFs.

**Transcriptional repression of a subset of canonical PRC1 targets preserves stem cell identity**

Recently, two major classes of PRC1 complexes have been described (6) on the basis of their biochemical composition. Canonical PRC1, which contains CBX proteins, is recruited on their targets in a PRC2-dependent manner. Noncanonical PRC1 complexes do not contain the CBX-containing subunits and are recruited independently from PRC2. They are characterized by the presence of different PCGF subunits and share the subunits RYBP (RING1 and YY1 Binding Protein) or YAF2 (YY1 Associated Factor 2). Different components of canonical and noncanonical PRC1 complexes are expressed in HFSCs (fig. S4A).

To investigate the ability of RING1B to enter both canonical and noncanonical complexes in HFSCs, we performed proximity ligation assay (PLA). Wild-type and dKO LGR5+ HFSCs from waxed mice have been sorted (fig. S4, B and C) and used to investigate the ability of RING1B to interact with RYBP (Fig. 3, F and G) or BMI1 (Fig. 3, H and I). Our data indicate that in HFSCs, both canonical and noncanonical complexes assemble, suggesting that the phenotype observed in dKO HFSCs could be the result of the impaired activity of different complexes.

To identify the common mechanisms through which PRC1 regulates cell fate determination in different stem cell populations, we performed chromatin immunoprecipitation sequencing (ChIP-seq)

analysis for RING1B in FACS-sorted activated LGR5+ stem cells purified 8 days from waxing (Fig. 4, A and B). This analysis identified nearly 3900 RING1B significant peaks that were mainly associated with promoter regions (Fig. 4C). This distribution closely resembles the RING1B chromatin association that we have found in ISCs (Fig. 4D). Since RING1A or RING1B can form distinct functional complexes that may localize differently along the genome (6), we first compared the genomic localization of RING1B in both HFSCs and ISCs in respect to the deposition of H3K27me3 to define Polycomb-repressed domains (9 and ISCs in respect to the deposition of H3K27me3 to define Polycomb-repressed domains (9, 28). We restricted the extent of overlap with the canonical PcG-repressed domains only to 20% of RING1B sites in HFSCs (Fig. 4E) and to 10% in ISCs (Fig. 4F), suggesting that a large fraction of RING1B activity is exerted independently of PRC2. In ESCs, H3K27me3 is enriched at promoters of developmental-related genes concomitantly with the deposition of the transcriptional activatory modification H3K4me3. This promoter status has been defined as “bivalent” or “poised” (29). Bivalency is resolved when ESCs are triggered to differentiate by the acquisition of a purely active (H3K4me3 only) or repressed (H3K27me3 only) state. We found that, while only 30% of H3K27me3 sites in HFSC are bivalent (coenriched with H3K4me3), this proportion expands in ISCs where it reaches 80% of all RING1B target promoters enriched for H3K27me3 (Fig. 4, G and H). We also observed a large fraction of RING1B-bound sites that lacks H3K27me3 but presents H3K4me3 deposition (Fig. 4, I and J). Accordingly, with the ability of RING1B to interact with subunits of both canonical and noncanonical complexes, we observed that in ISCs, nearly 70% of RYBP peaks colocalize with RING1B (Fig. 4K), but only a small percentage (11%) of the co-occupied regions harbor H2AK119Ub (Fig. 4L). Those regions characterized by the presence of RING1B and H2AK119Ub are also occupied by CBX8, a canonical PRC1 subunit, and are decorated by PRC2-dependent H3K27me3 mark (Fig. 4, M and N). These data suggest that both canonical and noncanonical PRC1 activities, which are not associated with H3K27me3 and H2AK119Ub, could contribute in the maintenance of stem cell identity.

To address this issue, we ranked all RING1B target promoters based on their expression in wild-type cells, and we compared their expression in PRC1-defective HFSCs and ISCs (Fig. 4O and fig. S5A). This analysis identified four classes of genes. Repressed genes in wild-type cells defined cluster 1 and were enriched for transcriptionally activated genes in Ring1a/b dKO HFSCs and ISCs. Genes with intermediate expression (clusters 2 and 3) showed no difference (Fig. 4O) or slightly decreased expression (fig. S5A) in Ring1a/b dKO cells. Highly expressed genes (cluster 4) were slightly down-regulated in Ring1a/b dKO HFSC. The distribution of H3K27me3, H2AK119Ub, and H3K4me3 (Fig. 4P and fig. S5B) identified genes belonging to cluster 1 as fully silenced through canonical Polycomb activities, as demonstrated by the presence of CBX8 (Fig. 4P). These sites are devoid of H3K4me3, which is instead enriched at all the other clusters (Fig. 4P and fig. S5B) where colocalizes with RING1B and RYBP (Fig. 4P). Accordingly, genes involved in development and differentiation were only enriched in cluster 1 (Fig. 4Q and fig. S5, C, E, and F). Despite the fact that these data support a prominent role for canonical versus noncanonical activities in maintaining cell identity in HFSCs and ISCs, it is important to stress that only a subset of RING1B+/H3K27me3+/H2AK119Ub targets become derepressed upon the loss of PRC1 activity in HFSCs and ISCs (Fig. 4R and fig. S5D). This suggests, first, that H3K27me3 is largely sufficient to prevent TF accessibility and activation of PcG targets and, second, that only a small proportion of PcG target genes contribute to the observed phenotypes.

**Loss of PRC1 activity activates epidermal-specific program**

To uncover direct mechanisms associated with PRC1 loss of activity, we focused our attention on RING1B targets that became derepressed in Ring1a/b dKO. This includes Ascl2 (Fig. 5A), which encodes for a TF previously shown to be sufficient and required to drive epidermal differentiation (30). To investigate whether a specific differentiation program is initiated upon PRC1 activity loss, we performed gene set enrichment analysis (GSEA) comparing signatures from different cells belonging to distinct skin compartments (31) against Ring1a/b dKO versus ctrl transcriptional outcome in HFSCs. This analysis showed that, together with the stem cell signature, genes involved in epidermal-specific transcriptional program became enriched in Ring1a/b dKO mice (Fig. 5B). Among them, Satb1, Krt14, Calm5, Itgam, and Gpdp2, together with Ascl2, were some of the known epidermal markers that are highly activated (Fig. 5, A, C, and D). We further scanned the Ascl2 promoter with LASAGNA-Search 2.0 (32) for putative TFs responsible for its activation and found several binding motifs that are recognized by the family of ZIC TFs (Fig. 5E). Note that different members of this TF family are also directly bound and derepressed in Ring1a/b dKO HFSCs (fig. S3F), establishing a positive feedback loop driving epidermal identity. Together, these results support a model in which PRC1 directly suppresses an epidermal-specific transcriptional program via suppression of master regulators of lineage specification, thus contributing to preserve HF identity.

**DISCUSSION**

The role of Polycomb complexes in maintaining adult stem cell identity has been investigated by several groups during the past 5 years. We recently reported that PRC1 and PRC2 play a crucial role in supporting intestinal homeostasis (8–10). Along the crypt-to-villus axis, the balance between secretory cells and enterocytes differentiation, transit-amplifying cell proliferation and stem cell maintenance are preserved by Polycomb complexes. In particular, PRC1 is critically required for ISC maintenance, and the loss of Ring1a/b subunits leads to stem cell exhaustion. Its activity is required to maintain repressed non–lineage-specific TFs, some of which are able to interfere with the ISC-specific transcriptional programs. Stem cell loss observed in Ring1a/B-deficient intestinal epithelium can therefore be ascribed not to the initiation of a defined transcriptional program but to the loss of stem cell–specific ones. To unveil general mechanisms underlying PRC1-dependent adult stem cell maintenance, we extended its analysis in proliferating HFSCs. Similar to what we previously described for ISCs, the loss of Ring1a/B in HFSCs markedly affects HF regeneration. This phenotypic convergence is mirrored at a transcriptional level by the up-regulation of non–lineage-specific genes, enriched for DNA binding TFs. We provide evidence that PRC1 associates at H3K27me33 promoters of repressed genes in the context of canonical complexes, characterized by the presence of CBX8 subunit and H2AK119Ub. At promoters of active genes, RING1B occupancy coincides with RYBP and low or undetectable H2AK119Ub levels, suggesting that noncanonical PRC1 complexes could play a role at these promoters that is largely independent from their ability to modify histone H2A. distribution has also been reported in murine ESCs, where H2AK119Ub1 and PRC2 co-occupy genes bound by CBX7/RING1B and are largely excluded by those regions exclusively bound by RYBP/RING1B (33). Note that, similar to ESCs, PRC1 localized on both repressed (canonical PcG targets) and active genes in both ISCs and HFSCs. This latter observation is in line with another recent report demonstrating a pivotal role of PRC1 during skin development (11). However, despite the fact that RYBP-containing PRC1 localizes to active promoters in both ISCs and HFSCs, very few of those active PRC1 targets score among the down-regulated genes, suggesting a marginal role of noncanonical complexes in preserving the expression of these target genes. This further restricts the specific phenotypes firstly described in ISCs and now documented in HFSCs to a more canonical PRC1 repressive activity. Our data demonstrate that several PcG direct targets became derepressed upon PRC1 loss of function and several of these targets can be directly linked to the observed phenotypic convergence. However, in HFSCs and ISCs, not all the PRC1 bound targets became activated upon RING1A/B loss. This suggests that, despite the idea that a general PRC1 role in maintaining repression of non-lineage-specific genes is, to some extent, conserved in cells of different developmental origin and tissues (i.e., HFSC, ESCs, and ISC), the transcriptional program triggered by its loss of function remains cell type dependent. This is likely due to the repertoire of available TFs in any given cell. Accordingly, among the different derepressed genes in Ring1a/b dKO HFSC, we found Ascl2, a DNA binding TF sufficient and required for epidermal differentiation (30).

Together, our data ultimately support the existence of a general role played by PRC1 to maintain adult stem cell identity that converge into a common phenotype with distinct cell type–specific mechanisms. This observation is of crucial importance not only to understand the role of Polycomb complexes in shaping adult tissues but also in different pathological settings, such as cancer, in which PcG is directly involved. The requirement of PcG during tumor development and progression, where a high level of cell heterogeneity can be observed, has been extensively reported, and several PcG

inhibitors entered clinical trials (1), 34). In this context, the efficacy (i.e., the consequences) of PcG inhibition could be cell type specific, as we describe for adult stem cells, and possibly dependent on the integrity of the signaling pathways and on the TF repertoire of the different cells.

**MATERIALS AND METHODS**

### Mouse models

Lgr5-specific conditional knockout mice were generated by crossing RingA−/−/RingBfl/fl (35), with LGR5-eGFP-IRESCreERT2 mice (36). These mice were crossed with Rosa26lox-stop-lox LacZ transgenic mice for in vivo lineage tracing (37). Genotyping was confirmed by polymerase chain reaction (PCR) of tail skin DNA. Cre-dependent recombination was induced performing three intraperitoneal injections of tamoxifen (Sigma-Aldrich) at 75 mg/kg.

Mice were maintained accordingly to the guidelines set out in Commission Recommendation 2007/526/EC, 18 June 2007, on guidelines for the accommodation and care of animals used for experimental and other scientific purposes. All experiments were performed in accordance with the Italian Laws (D.L.vo 116/92 and following additions), which enforces EU Directive 86/609 (Council Directive 86/609/EEC of 24 November 1986 on the approximation of laws, regulations, and administrative provisions of the member states regarding the protection of animals used for experimental and other scientific purposes).

### HF purification

LGR5+ cells were purified from back skin of treated mice at different time points. Subcutaneous fat and the blood vessels were removed, and the skin was digested using collagenase (2.5 mg/ml) in Dulbecco’s modified Eagle’s medium (DMEM) for 45 min. HFs were scraped off and incubated for 10 min at 37°C with 2.5% trypsin in phosphate-buffered saline (PBS) and deoxyribonuclease I (DNase1; 1600 U/ml). Genotyping was confirmed by polymerase chain reaction (PCR) of tail skin DNA. Cre-dependent recombination was induced performing three intraperitoneal injections of tamoxifen (Sigma-Aldrich) at 75 mg/kg.

Mice were maintained accordingly to the guidelines set out in Commission Recommendation 2007/526/EC, 18 June 2007, on guidelines for the accommodation and care of animals used for experimental and other scientific purposes. All experiments were performed in accordance with the Italian Laws (D.L.vo 116/92 and following additions), which enforces EU Directive 86/609 (Council Directive 86/609/EEC of 24 November 1986 on the approximation of laws, regulations, and administrative provisions of the member states regarding the protection of animals used for experimental and other scientific purposes).

### Proximity ligation assay

Anagen-induced sorted LGR5 HFSCs were spotted in Cell-Tak (Corning)-coated coverslip, and PLA was performed using Sigma-Aldrich Duolink In Situ Orange Starter Kit Mouse/Rabbit following the manufacturer’s instruction protocol. Anti-RING1B antibody (homemade), anti-RYBP (AB3637, Millipore), and anti-BMI1 (homemade) primary antibodies were used.

### Histology and lineage tracing

Freshly obtained back skin samples were collected at the indicated time point and were immediately prefixed for 30 min at room temperature in PBS containing 0.2% gluteraldehyde, 0.02% NP-40, and 2% PFA. Samples were washed three times for 10 min each with PBS and incubated for 30 min with the equilibration buffer (2 mM MgCl2, 0.02 NP-40, and 0.1% sodium deoxycholate in PBS). Samples were stained overnight at room temperature using 5 mM K3Fe(CN)6, 5 mM K4Fe(CN)6, and X-Gal (1 mg/ml) in equilibration buffer. Stained skin were washed abundantly with PBS at room temperature and then fixed overnight in 4% PFA in PBS before paraffin embedding. Five-micrometer sections were obtained, rehydrated, and nuclei-counterstained with Nuclear Fast Red solution for 10 min at room temperature. For histological analysis, freshly isolated back skin samples were fixed in 4% formaldehyde overnight, paraffin-embedded, and stained with hematoxylin and eosin Y. Images were acquired using Olympus BX51 or Leica DM6 widefield microscope.

### RNA sequencing

FACS-sorted cells were collected in 0.5-ml tubes and processed directly following Smart-seq2 protocol (38) with minor modifications. Briefly, 3000 cells per sample were collected directly and lysed in 2 μl of lysis buffer [0.2% Triton X-100 and ribonuclease inhibitor (4 U/μl)]. One microliter of 10 μM oligo-dT30Vn and 1 μl of 10 mM deoxyribonucleotide triphosphate were added, and the samples were incubated for 3 min at 72°C. Reverse transcriptase step was performed using SuperScript III reverse transcriptase enzyme (Invitrogen). Preamplification of the obtained complementary DNA (cDNA) was performed using KAPA Taq HotStart enzyme with High-Fidelity Buffer. Preamplified cDNA was purified using AMPure beads (Agencourt AMPure XP, Beckman Coulter), and the quality was checked using Bioanalyzer (Agilent). Two nanograms of cDNA was tagmented with 100 ng of homemade Tn5 enzyme and further amplified using KAPA HiFi HotStart Kit. Tagmented, amplified DNA was sequenced using Illumina HiSeq2000.

### ChIP sequencing

LGR5+ HFSCs were purified as previously described from anagen-synchronized HFs of Ring1a/b+/− mice and were extracted following the protocol previously described. A total of 2.5 million cells were used for ChIP-seq as previously described (9). Sonicated chromatin was incubated with 10 μg of rabbit anti-RING1B antibody (homemade), anti-H2AK119Ub1 (8240, Cell Signaling Technology), anti-RYBP (AB3637, Millipore), and anti-CBX8 (39) overnight, and the immunocomplexes recovered using protein A-conjugated magnetic beads (Dynabeads, Life Technologies). Purified chromatin was decross-linked overnight in 0.1 M NaHCO3 and 1% SDS. Decross-linked DNA was purified. ISC-specific H3K4me3 ChIP-seq profile was obtained as previously described (9) using 5 μg of anti-H3K4Me3 antibody (catalog no. 39159, Active Motif).
RNA-seq analysis
Reads were aligned to the mouse reference genome mm9 using TopHat v2.1.1 (40) with parameters --no-coverage-search and --library-type fr-unstranded. PCR duplicates were removed using Picard (http://broadinstitute.github.io/picard/). Gene counts were calculated using HTSeq-count v0.8.0 (41) with parameters --stranded=no --mode=intersection-nonempty using ReSeq mm9 annotation downloaded from the University of California, Santa Cruz. Differential expression analyses were performed using the R package DESeq2 v1.20 (42) using default parameters. Genes with an absolute log2 fold change of 1 and false discovery rate of <0.1 were considered as differentially expressed. Gene enrichment analysis on down- and up-regulated genes was performed using DAVID 6.8 (43). A pranked GSEA (44) was performed using gene lists (Signature Gene Lists) from multiple skin cell populations obtained from (31). The analysis was performed using default parameters (weighted as enrichment statistic) and ranking the input gene list using log2 fold-change data obtained from DESeq2.

To assess the expression of differentially expressed genes in Ring1A-
B/− versus wild-type HFSC in other mouse tissues, we used public RNA-seq data (bam files) deposited by ENCODE at (http://hgdownload.soe.ucsc.edu/goldenPath/mm9/encodeDCC/wgEncodeLclRnaSeq/). Bam files were processed with the pipeline described previously, and RPKM (Read Per Kilobase of Milion Mapped Reads) data were normalized with the function normalize.quantiles() from the R package preprocessCore (https://github.com/bmbolstad/preprocessCore).

ChIP-seq analysis
Reads were aligned to the mouse reference genome mm9 using Bowtie v1.2.2 (45) with default parameters and not allowing multimapping (-m1). PCR duplicates were removed using Picard (http://broadinstitute.github.io/picard/). Peaks were called using MACS2 v2.1.1 (46) with parameters -g mm --nomodel -p 1e-10 –B.

Genomic peak annotation was performed using the R package preprocessCore (https://github.com/bmbolstad/preprocessCore). intersection-nonempty (47) with parameters -B.

For heatmap representation of ChIP-seq signal, bigwig files, with input signal subtracted, were generated using the function scaleFactors with input signal subtracted, were generated using the function scaleFactors (48).

For heatmap representation of ChIP-seq signal, bigwig files, with input signal subtracted, were generated using the function scaleFactors with input signal subtracted, were generated using the function scaleFactors (48).
