Innovative method for CO\textsubscript{2} fixation and storage

Kenji Sorimachi

The concentration of CO\textsubscript{2} in Earth's atmosphere has been gradually increasing since the Industrial Revolution, primarily as a result of the use of fossil fuels as energy sources. Although coal and oil have been vital to the development of modern civilization, it is now recognized that atmospheric CO\textsubscript{2} levels must be reduced to avoid the serious effects of climate change, including natural disasters. Consequently, there is currently significant interest in developing suitable methods for the fixation of CO\textsubscript{2} in the air and in exhaust gases. The present work demonstrates a simple yet innovative approach to the chemical fixation of extremely low and very high CO\textsubscript{2} concentrations in air, such as might result from industrial sources. This process is based on the use of aqueous solutions of the water-soluble compounds NaOH and CaCl\textsubscript{2}, which react with CO\textsubscript{2} to produce the harmless solids CaCO\textsubscript{3} (limestone) and NaCl (salt) via intermediates such as NaHCO\textsubscript{3} and Na\textsubscript{2}CO\textsubscript{3}. The NaCl generated in this process can be converted back to NaOH via electrolysis, during which H\textsubscript{2} (which can be used as a clean energy source) and Cl\textsubscript{2} are produced simultaneously. Additionally, sea water contains both NaCl and CaCl\textsubscript{2} and so could provide a ready supply of these two compounds. This system provides a safe, inexpensive approach to simultaneous CO\textsubscript{2} fixation and storage.

Although Earth has undergone many periods of significant environmental change over time, the planet's environment has been unusually stable for the past 10,000 years\textsuperscript{1}. During this time, various natural systems regulated the Earth's climate and maintained the conditions that enabled human development. However, these regulatory systems have been greatly disturbed, and the planet may be nearing a threshold beyond which unpredictable environmental changes may occur, such as increases in the mean global temperature\textsuperscript{2}. To reduce atmospheric CO\textsubscript{2} concentrations as a means of mitigating such effects, the so-called Paris Agreement was reached at the United Nations Climate Change Conference (COP20) in 2015. This agreement was based on the requirement to keep the increase in the mean global temperature below 2 °C relative to the temperature prior to the Industrial Revolution, and preferably less than 1.5 °C. At present, this goal is challenging based solely on the development of carbon-neutral energy systems. Even so, President Elect Joe Biden has stated that the United States of America will rejoin the Paris Agreement (rejoined historically today, January 20, 2021) and the current Prime Minister of Japan, Yoshihide Suga, has declared that Japan will achieve a carbon-neutral society by 2050. Additionally, the President of the People's Republic of China, Xi Jinping, has declared that China will be carbon neutral by 2060. Even so, because the present atmospheric CO\textsubscript{2} concentration is quite high, there are ongoing efforts to reduce the accumulated CO\textsubscript{2} so as to prevent a climate change crisis. Climatologists have warned that a significant reduction in the level of CO\textsubscript{2} in Earth's atmosphere is required over the next decade\textsuperscript{3}; therefore, it is necessary to immediately begin this process. The urgency of this work has been communicated by climate change activists such as Greta Thunberg, and “Fridays for Future” events have been held worldwide.

Although renewable energy sources, including solar radiation and wind, can result in reduced CO\textsubscript{2} emissions, these alternative systems still require energy expenditure and may also involve CO\textsubscript{2} production. Additionally, these renewable energy approaches do not remove CO\textsubscript{2} that has already accumulated in the atmosphere, nor do they address the ongoing generation of CO\textsubscript{2} from exhaust gases and industrial sources. Thus, even if a carbon-neutral society could be immediately achieved, the accumulated atmospheric CO\textsubscript{2} would not be reduced. For these reasons, it is important to lower the CO\textsubscript{2} level currently in Earth's atmosphere and to develop practical means of doing so as soon as possible. For CO\textsubscript{2} storage, geo-sequestration by injecting CO\textsubscript{2} into underground geological formations, such as oil fields, gas fields, and saline formations, has been suggested\textsuperscript{3,4}, although these systems are still projects for the future.

Plants consume large quantities of CO\textsubscript{2} based on photosynthesis, in which CO\textsubscript{2} and H\textsubscript{2}O are converted to carbohydrates using chlorophyll under sunlight. However, the planet's largest forest, the Amazon, which greatly contributes to the removal of atmospheric CO\textsubscript{2}, is continually shrinking because of commercial development.

\textsuperscript{1}Research Laboratory, Gunma Agriculture and Forest Development, Takasaki, Gunma 370-0854, Japan. \textsuperscript{2}Present address: Bioscience Laboratory, Environmental Engineering, Co., Ltd., 1-4-6 Higashi-Kaizawa, Takasaki, Gunma 370-0041, Japan. email: kenjis@jcom.home.ne.jp
and serious fires. CO₂ also dissolves in the oceans to form H₂CO₃, HCO₃⁻ and CO₃²⁻, and there is approximately 50 times as much carbon dissolved in the oceans as exists in the atmosphere. Conversely, all living organisms produce CO₂ during respiration, such that the rates of CO₂ consumption and production were balanced before human activities produced huge amounts of CO₂. Certain CO₂ derivatives are used industrially and in medicine. The synthesis of methanol from CO₂ is particularly important because methanol is a primary raw material for the production of numerous other chemicals. For example, our own group recently found that NaHCO₃ and Na₂CO₃ accelerate glucose consumption in cultured cells. These materials improve serum glucose levels in diabetes mellitus patients. However, the rate of usage of CO₂ compounds in such applications is obviously much smaller than the rate of CO₂ production.

CaCO₃ can be used as a component of concrete, and CO₂ can also be reacted to generate important compounds such as methanol on an industrial scale, although the CO₂ must first be captured and concentrated or fixed in some manner. CaCO₃ is also readily converted to CO₂ by reaction with HCl and other acids. Additionally, it should be noted that large amounts of CaCO₃ are produced naturally as coral or in the form of limestone.

CO₂ can be captured from the ambient air or from flue gas via several techniques, including absorption, adsorption and membrane gas separation. Absorption with amines is currently the dominant technology, while membrane and adsorption processes are still in the developmental stages with the construction of primary pilot plants anticipated in the near future. Recently, it was reported that an amine compound, spiroaziridine oxindole, fixed efficiently CO₂ under near ambient conditions and released CO₂ under mild conditions. However, to the best of our knowledge, these methods alone cannot achieve the necessary worldwide reductions in atmospheric CO₂.

Results and discussion

CaCO₃ precipitation. It is known that CO₂ is absorbed by alkaline solution. In the present work, CO₂ was bubbled through an initially clear solution (Fig. 1a) containing 0.05 N NaOH and 0.05 M CaCl₂ to form an immediate white precipitate (Fig. 1b).

\[
2\text{NaOH} + \text{CaCl}_2 + \text{CO}_2 \rightarrow \text{CaCO}_3 + \text{H}_2\text{O} + 2\text{NaCl}
\]

In other trials, varying the NaOH concentration between 0 and 0.5 N in the presence of 0.05 M CaCl₂ was found to generate a white precipitate above 0.2 N NaOH even in the absence of CO₂. Because this precipitate resulted from the formation of Ca(OH)₂, the
potential for CO2 incorporation in the form of CaCO3 was minimal under these conditions. Conversely, solutions with lower NaOH concentrations (from 0.05 to 0.1 N NaOH) together with 0.05 M CaCl2 remained clear, while the addition of CO2 bubbles produced a white precipitate (Fig. 2a). Under these conditions, CaCO3 precipitation occurred in the presence of CaCl2, which means that high NaOH concentrations were reduced by the formation of a Ca(OH)2 precipitate. However, prolonged bubbling with CO2 decomposed the CaCO3 precipitates to form Ca(HCO3)2, which is water soluble. As the concentration of CaCl2 was changed from 0 to 0.5 M, the amount of white precipitate was found to plateau at 0.05 M CaCl2 (Fig. 2b).

One step CO2 fixation. The CO2 concentration in a 2-L bottle made of poly(ethylene terephthalate) (PET) was monitored to determine whether a solution containing 0.05 N NaOH and 0.05 M CaCl2 reduced the level of CO2. These trials showed that the CO2 reduction was clearly correlated with the time span over which the solution remained in the bottle and in contact with the internal atmosphere (Fig. 3a). Approximately 60% and 80% of the initial CO2 was removed after 15- and 60-min treatments, respectively. After allowing the plastic bottle to sit overnight, the CO2 in the bottle was completely removed. Thus, chemical fixation of CO2 emission, regardless of volume/concentration of CO2 could be efficiently captured and fixed by a solution containing 0.05 N NaOH and 0.05 M CaCl2. Laying the plastic bottle on its side increased the surface area of the solution and thus increased the CO2 removal rate (Fig. 3b).

At a high CO2 concentration of approximately 15%, the addition of 50 mL of a solution containing 0.05 N NaOH and 0.05 M CaCl2, followed by vigorous shaking of the 2-L bottle for 30 s by hand reduced the CO2 concentration to 10% (Fig. 3c). A further slight reduction of the CO2 level after the initial rapid removal is attributed to the presence of insufficient quantities of NaOH and CaCl2. The pH of the solution after 24 h and following the third addition was 6.5, while that of the initial fresh solution was 12.19. These results indicate that the NaOH in the solution was completely consumed.

2NaOH + CaCl2 → Ca(OH)2 + 2NaCl
Two steps CO₂ fixation. In the above trials, a solution containing low concentrations of NaOH and CaCl₂ was used in a one step process. When using high NaOH concentrations (above 0.2 N), the CO₂ should first be treated solely with NaOH to prevent the formation of Ca(OH)₂. This produces a solution of NaHCO₃ and Na₂CO₃ to which CaCl₂ can be added after reducing the NaOH concentration to less than 0.1 N. The latter method is based on two steps and allows the use of high concentrations of NaOH and CaCl₂.

Fog formation by absorbents. Because increasing the surface area of the highly concentrated NaOH solution is also important to ensuring efficient absorption of CO₂, the generation of a fog can be beneficial. The formation of a fog greatly increases the liquid surface area and results in more rapid CO₂ removal in the plastic bottle (Fig. 4a). In experiments using a chimney model, when the chimney contained high CO₂ concentrations, the amounts of NaOH and CaCl₂ in the solution were insufficient to react with all the CO₂ at a gas flow rate of approximately 110 cm³/s (Fig. 4b). Thus, the solution could only capture a relatively small amount of the CO₂ in the chimney model.

Bubbling of CO₂ gas. The area over which the reagent solution interacted with CO₂ could also be increased by first passing the test gases through a porous stone to form bubbles. In these trials, a poly(vinyl chloride) pipe (40 mm in diameter and 50 cm in height) was partially filled with 250 mL each of aqueous solutions containing 0.1 N NaOH and 0.1 M CaCl₂. Following this, the test gas was bubbled upwards through the solution at a flow
rate of approximately 20 mL/s after passing through the porous stone at the bottom of the pipe. Under these conditions, the CO₂ contained in the air was completely absorbed by the solution (Fig. 5a). In trials using this same apparatus with a very high CO₂ concentration, the level was reduced from an initial value of 10–2.5% (Fig. 5b). These data indicate that this concept could be employed to reduce high CO₂ levels in the exhaust streams from industrial operations such as thermal power plants and incinerators.

Diagram showing the proposed CO₂ fixation process. One means of producing NaOH on an industrial scale is the electrolysis of an aqueous NaCl solution. The products of this newly developed CO₂ fixation system based on NaOH and CaCl₂ are CaCO₃ and NaCl, and this NaCl could therefore be subsequently converted to NaOH, H₂ and Cl₂ via an electrolytic process. Thus, CO₂ could be captured using this system while simultaneously producing H₂ and Cl₂ (Fig. 6). Additionally, this process could potentially be integrated with existing generator systems based on atomic, thermal, solar, wind, hydro or wave power, and natural seawater could be used instead of an artificial NaCl solution in the electrolysis process.

Conversely, the system presented in Fig. 6 is based on both CO₂ fixation and NaCl electrolysis. Because the efficient absorption of CO₂ with NaOH micro-droplets requires a large volume, while the electrolysis of a NaCl solution does not, a new CO₂ capture plant design was developed, as shown in Fig. 7. This plant is intended to continually capture CO₂ from the atmosphere or from exhaust gases. Using a large chamber equipped with spray nozzles, CO₂ can be captured efficiently by droplets of the NaOH solution. As indicated in the figure, this chamber could have various geometries. The cylindrical and meandering shapes would be applicable to either reclining or standing structures, while the other morphologies would be suitable only for a standing structure. This system could also be combined with the NaOH generating process described in the preceding section.

Recently, plastic waste has been shown to be a significant environmental pollutant, and micro-plastics have been found to affect marine organisms⁷⁶. A small portion of the plastics that are used daily in human activities are recycled, while the remainder is simply treated as waste. Many of these materials could be incinerated but instead are typically sent to landfills. However, if a simple method of fixing CO₂ becomes available, this waste could be readily disposed of by burning without any environmental concerns and with the potential to generate energy. In addition, the current COVID-19 pandemic has resulted in vast quantities of waste materials potentially contaminated with the virus. It would be helpful to be able to burn contaminated plastic-based medical

Figure 4. CO₂ concentration changes obtained using a spray. A solution containing 0.05 N NaOH and 0.05 M CaCl₂ was sprayed 10 times at 5-s intervals to provide a total volume of approximately 4 mL. (a) The solution was sprayed into a 2-L plastic PET bottle and (b) into a chimney model made from two milk boxes. In the latter case, the air and CO₂ flow rates were 100 and 10 cm³/s, respectively. All values are the means plus or minus one standard deviation based on either six or ten replicates.
waste as a means of limiting the spread of infection. At present, chemical absorption using organic amines is typically employed to capture CO₂ emitted from thermal power plants, but liberating CO₂ from these complexes requires heat treatment that induces degradation. Because this treatment itself produces CO₂, a new method that fixes CO₂ would be highly beneficial. The present method employing inorganic compounds generates a stable product, based on the neutralization of NaOH along with the formation of CaCO₃ and NaCl, both of which are harmless, stable natural compounds.

This technique is applicable to thermal power plants, chemical plants, large ships, combustion operations, incinerators and automobiles. Under strict regulations for air pollution, exhaust of oxide of nitrogen (NOₓ) and sulfur dioxide (SO₂) which have great influence on environment and human health from coal combustion²¹,²² have been strongly prohibited by law. Contrary, there is no CO₂ emission control, and this resulted in accumulation of atmospheric CO₂ since the Industrial Revolution. Using this process, atmospheric CO₂ can be spontaneously fixed based on a simple apparatus at various locations to generate CaCO₃. This newly developed and

facile system, which does not require organic chemicals, has minimal environmental impact and is completely sustainable, and so is expected to provide a means of reducing atmospheric CO₂ levels so as to mitigate climate change. At present, there is worldwide recognition that climate change has become a crisis². Because humans “who are the most evolved organisms”²³,²⁴ are responsible for this crisis, we have a moral duty to address the situation through global cooperation.

Methods

Chemicals. Reagent grade NaOH and CaCl₂ were purchased from Wako-Junyaku Kogyo (Tokyo, Japan). Milli-Q water was used throughout the experiments.

CO₂ fixation. The reaction solution containing 0.05 N NaOH and 0.05 M CaCl₂ was prepared in a commercial 2-L plastic PET bottle or a commercially available 1.4-L octagonal plastic bottle and the bottles were allowed to stand or were shaken for the stated periods.

In the fog trials, approximately 4 mL of the solution was sprayed into a 2-L plastic PET bottle, after which the CO₂ concentration (in ppm) was measured using an RI-85 instrument (RIKEN). The chimney model was prepared by combining two 1-L paper milk boxes, after which air (at approximately 100 cm³/s) and CO₂ (approximately 10 cm³/s) were supplied into the lower box. A layer of gauze was placed between the two boxes and approximately 4 mL of the solution was sprayed into the middle part of the lower box. The CO₂ concentration (in %) was subsequently determined at the central point of the upper box using an XP-3140 instrument (COSMOS).
