Neutrinos may be pseudo-Dirac states, such that each generation is actually composed of two maximally-mixed Majorana neutrinos separated by a tiny mass difference. The usual active neutrino oscillation phenomenology would be unaltered if the pseudo-Dirac splittings are \(\delta m^2 \lesssim 10^{-12} \text{ eV}^2\); in addition, neutrinoless double beta decay would be highly suppressed. However, it may be possible to distinguish pseudo-Dirac from Dirac neutrinos using high-energy astrophysical neutrinos. By measuring flavor ratios as a function of L/E, mass-squared differences down to \(\delta m^2 \sim 10^{-18} \text{ eV}^2\) can be reached. We comment on the possibility of probing cosmological parameters with neutrinos.

PACS numbers: 95.85.Ry, 96.40.Tv, 14.60.Pq

Are neutrinos Dirac or Majorana fermions? Despite the enormous strides made in neutrino physics over the last few years, this most fundamental and difficult of questions remains unanswered. The observation of neutrinoless double beta decay would unambiguously signal Majorana mass terms and hence lepton number violation. If no neutrinoless double beta decay signal is seen, it may be tempting to conclude that neutrinos are Dirac particles, particularly if there is independent evidence from tritium beta decay or cosmology for significant neutrino masses. However, Majorana mass terms may still exist, though their effects would be hidden from most experiments. Observations with neutrino telescopes may be the only way to reveal their existence.

The generic mass matrix in the \((\nu_L, (\nu_R)^C)\) basis is

\[
\begin{pmatrix}
  m_L & m_D \\
  m_D & m_R
\end{pmatrix}
\]

(1)

A Dirac neutrino corresponds to the case where \(m_L = m_R = 0\), and may be thought of as the limit of two degenerate Majorana neutrinos with opposite CP parity. Alternatively, we may form a pseudo-Dirac neutrino by the addition of tiny Majorana mass terms \(m_L, m_R \ll m_D\), which have the effect of splitting the Dirac neutrino into a pair of almost degenerate Majorana neutrinos, each with mass \(\sim m_D\). The mixing angle between the active and sterile states is very close to maximal, \(\tan(2\theta) = 2m_D/(m_R - m_L) \gg 1\), and the mass-squared difference is \(\delta m^2 \approx 2m_D(m_L + m_R)\). For three generations, the mass spectrum is shown in Fig. 1. The mirror model can produce a very similar mass spectrum.

The current theoretical prejudice is for the right-handed Majorana mass term to be very large, \(m_R \gg m_D\), giving rise to the see-saw mechanism. Then the right-handed states are effectively hidden from low energy phenomenology, since their mixing with the active states is suppressed through tiny mixing angles. This is desirable, since no direct evidence for right-handed (sterile) states has been observed (we treat both solar and atmospheric neutrinos as active-active transitions, and do not attempt to explain the LSND \footnote{The LSND experiment observed an anomaly that has not been explained as of this writing.} anomaly). If right-handed neutrinos exist, where else can they hide? An alternative to the see-saw mechanism is pseudo-Dirac neutrinos. Here, although the mixing between active and sterile states is maximal, such neutrinos will, in most cases, be indistinguishable from Dirac neutrinos, as very few experiments can probe very tiny mass-squared differences.

In the Standard Model, \(m_D\) arises from the conventional Yukawa couplings and hence its scale is comparable to other fermion masses. In the see-saw model, \(m_R\) is identified with some large GUT or intermediate scale mass, and thus small neutrino masses are achieved. For

![Diagram](https://example.com/diagram.png)

FIG. 1: The neutrino mass spectrum, showing the usual solar and atmospheric mass differences, as well as the pseudo-Dirac splittings in each generation (though shown as equal, we assume they are independent). The active and sterile components of each pseudo-Dirac pair are \(\nu_{ja}\) and \(\nu_{js}\), and are maximal mixtures of the mass eigenstates \(\nu^+\) and \(\nu^-\). Neither the ordering of the active neutrino hierarchy, nor the signs of the pseudo-Dirac splittings, has any effect on our discussion.
pseudo-Dirac masses, on the other hand, we need both $m_L$ and $m_R$ to be small compared to $m_D$. The smallness of $m_L$ with respect to $m_D$ follows from their $SU(2)_L$ properties; the former breaks it while the latter is invariant under it. A similar property with respect to a $SU(2)_R$ (obtained with a low-energy $SU(2)_L \otimes SU(2)_R$ symmetry group) may also make $m_R$ small compared to $m_D$. Specific examples which achieve precisely this are given in Ref. [6]. While there still remains the problem of keeping $m_D$ itself small enough, so that the physical neutrino masses are tiny compared to the other fermions, there are a number of suggestions of how this may arise [7, 8, 9].

Astronomical-scale baselines ($L \gtrsim E/\delta m^2$) will be required to uncover the oscillation effects of very tiny $\delta m^2$ [4, 10]. Crocker, Melia, and Volkas have considered possible distortions to the $\nu_6$ spectrum [11]. Fig. 2 shows the range of neutrino mass-squared differences that can be probed with different classes of experiments. Present limits on pseudo-Dirac splittings arise from the solar and atmospheric neutrino measurements. Splittings of less than about $10^{-12}$ eV$^2$ (for $\nu_1$ and $\nu_2$) have no effect on the solar neutrino flux [4], while a pseudo-Dirac splitting of $\nu_3$ could be as large as about $10^{-5}$ eV$^2$ before affecting the atmospheric neutrinos.

Note that models with light sterile neutrinos often conflict with big bang nucleosynthesis limits on the number of light degrees of freedom in thermal equilibrium in the early universe. However, the sterile component of each Pseudo-Dirac pair will not be populated, provided the mass splitting of each pair is sufficiently small, as will be the case for the examples we consider here.

**Formalism.**— Let $(\nu_1^+, \nu_2^+, \nu_3^+, \nu_1^-, \nu_2^-, \nu_3^-)$ denote the six mass eigenstates, where $\nu^+$ and $\nu^-$ are a nearly-degenerate pair. A $6 \times 6$ mixing matrix rotates the mass basis into the flavor basis $(\nu_e, \nu_\mu, \nu_\tau; \nu'_e, \nu'_\mu, \nu'_\tau)$. In general, for six Majorana neutrinos, there would be fifteen rotation angles and fifteen phases. However, for pseudo-Dirac neutrinos, Kobayashi and Lim [2] have given an elegant proof that the $6 \times 6$ matrix $V_{KL}$ takes the very simple form (to lowest order in $\delta m^2/m^2$):

$$V_{KL} = \begin{pmatrix} U & 0 \\ 0 & U_R \end{pmatrix} \cdot \begin{pmatrix} V_1 & iV_4 \\ V_2 & -iV_4 \end{pmatrix}, \tag{2}$$

where the $3 \times 3$ matrix $U$ is just the usual mixing matrix determined by the atmospheric and solar observations, the $3 \times 3$ matrix $U_R$ is an unknown unitary matrix, and $V_1$ and $V_2$ are the diagonal matrices $V_1 = \text{diag}(1, 1, 1)/\sqrt{2}$, and $V_2 = \text{diag}(e^{-i\phi_1}, e^{-i\phi_2}, e^{-i\phi_3})/\sqrt{2}$. The $\phi_i$ are arbitrary phases. As a result, the three active neutrino states are described in terms of the six mass eigenstates as:

$$\nu_{\alpha L} = U_{\alpha j} \frac{1}{\sqrt{2}} (\nu_j^+ + i\nu_j^-). \tag{3}$$

The nontrivial matrices $U_R$ and $V_2$ are not accessible to active flavor measurements. The flavor conversion probability can thus be expressed as

$$P_{\alpha\beta} = \frac{1}{4} \left| \sum_{j=1}^{3} U_{\alpha j} \left( e^{i(m_j^+)^2 L/2E} + e^{i(m_j^-)^2 L/2E} \right) U_{\beta j}^* \right|^2. \tag{4}$$

The flavor-conserving probability is also given by this formula, with $\beta = \alpha$. Hence, in the description of the three active neutrinos, the only new parameters beyond the usual three angles and one phase are the three pseudo-Dirac mass differences, $\delta m_j^2 \equiv (m_j^+)^2 - (m_j^-)^2$. In the limit that $\delta m_j^2$ are negligible, the oscillation formulas reduce to the standard ones and there is no way to discern the pseudo-Dirac nature of the neutrinos.

We assume that the neutrinos oscillate in vacuum. The matter potential from relic neutrinos can affect the astrophysical neutrino oscillation probabilities, but only if the neutrino-antineutrino asymmetry of the background is large, of order 1 [12]. For present limits on that asymmetry, of order 0.1 [13], or for less extreme redshifts than assumed in Ref. [12], matter effects are negligible.

Supernova neutrinos from distances exceeding...
where $w_\alpha$ is the relative flux of $\nu_\alpha$ at the source, such that $\sum_\alpha w_\alpha = 1$. The probability for a neutrino telescope to measure flavor $\nu_\beta$ is then $P_\beta = \langle \nu_\beta | \rho | \nu_\beta \rangle$, which becomes

$$P_\beta = \sum_\alpha w_\alpha \sum_{j=1}^3 |U_{\alpha j}|^2 |U_{\beta j}|^2 \left[ 1 - \sin^2 \left( \frac{\delta m_j^2 L}{4E} \right) \right].$$

In the limit that $\delta m_j^2 \to 0$, Eq. (6) reproduces the standard expressions. The new oscillation terms are negligible until $E/L$ becomes as small as the tiny pseudo-Dirac mass-squared splittings $\delta m_2^2$.

Since $|U_{\alpha3}|^2 \simeq 0$, the mixing matrix $U$ for three active neutrinos is well approximated by the product of two rotations, described by the “solar angle” $\theta_{\text{solar}}$ and the “atmospheric angle” $\theta_{\text{atm}} \simeq 45^\circ$. The pion production and decay chain at the source produces expected fluxes of $w_\tau = 1/3$ and $w_{\mu} = 2/3$. In the absence of pseudo-Dirac splittings, it is well known \[14\] that this results in $P_\beta \simeq 1/3$ for all flavors, thus the detected flavor ratios are $\nu_e : \nu_\mu : \nu_\tau = 1 : 1 : 1$. Here and elsewhere, this $\nu_\mu - \nu_\tau$ symmetry is obtained when $\theta_{\text{atm}} = 45^\circ$ and $U_{\alpha3} = 0$. If pseudo-Dirac splittings are present, we thus expect

$$\delta P_\beta = \frac{1}{3} \left[ |U_{\alpha1}|^2 \chi_1 + |U_{\beta2}|^2 \chi_2 + |U_{\beta3}|^2 \chi_3 \right],$$

where $\delta P_\beta \equiv P_\beta - \frac{1}{3}$, and we have defined, for shorthand,

$$\chi_j = \sin^2 \left( \frac{\delta m_j^2 L}{4E} \right).$$

In the absence of pseudo-Dirac terms, flavor democracy is expected. However, the pseudo-Dirac splittings lead to an oscillatory, flavor-dependent, reduction in flux, allowing us to test the possible pseudo-Dirac nature of the neutrinos with neutrino telescopes. The signatures are flavor ratios which depend on astronomically large $L/E$.

As a representative value, we take $\theta_{\text{solar}} = 30^\circ$. Then the flavors deviate from the democratic $1/3$ value by

$$\delta P_\nu = \frac{1}{3} \left[ \frac{1}{4} \chi_1 + \frac{3}{4} \chi_2 \right],$$

$$\delta P_\mu = \delta P_\tau = -\frac{1}{3} \left[ \frac{1}{8} \chi_1 + \frac{3}{8} \chi_2 + \frac{1}{2} \chi_3 \right].$$

The latter equality is due to the $\nu_\mu - \nu_\tau$ symmetry.

We show in Table I how the $\nu_e : \nu_\mu$ ratio is altered if we cross the threshold for one, two, or all three of the pseudo-Dirac oscillations. The flavor ratios deviate from $1 : 1$ when one or two of the pseudo-Dirac oscillation modes is accessible. In the ultimate limit where $L/E$ is so large that all three oscillating factors have averaged to $1/2$, the flavor ratios return to $1 : 1$, with only a net suppression of the measurable flux, by a factor of $1/2$.

It was recently pointed out that neutrino flavor ratios will deviate significantly from $1:1$ if one or two of the active neutrino mass-eigenstates decay \[15\]. The decay scenario bears some resemblance to that presented here. In particular, if there is a range of $L/E$ values where the one or two heavier mass states have oscillated with their pseudo-Dirac partners, but the light state has not, then half of the heavy states will have disappeared, to be compared with the complete disappearance expected from unstable neutrinos \[15\]. The effects of pseudo-Dirac mass differences are much milder and will require more accurate flavor measurements than for decays \[15\]. In addition, the active-active mixing angles \[17\] will need to be known independently. A detailed analysis of the prospects for measuring flavor ratios in km-scale neutrino telescopes has been performed in Ref. \[16\]. This study shows that it will be very challenging for km-scale experiments to sensitively test the pseudo-Dirac scenario, and larger experiments are likely to be necessary.

**Neutrinoless Double Beta Decay.—** Since the two mass eigenstates in each pseudo-Dirac pair have opposite CP parity, no observable neutrinoless double beta decay

---

**TABLE I: Flavor ratios $\nu_\alpha : \nu_\beta$ for various scenarios.** The numbers $j$ under the arrows denote the pseudo-Dirac splittings, $\delta m_j^2$, which become accessible as $L/E$ increases. Oscillation averaging is assumed after each transition $j$. We have used $\theta_{\text{atm}} = 45^\circ$, $\theta_{\text{solar}} = 30^\circ$, and $U_{\alpha3} = 0$. 

| $\delta P_\nu$ | $\delta P_\mu$ | $\delta P_\tau$ |
|----------------|----------------|----------------|
| $1 : 1$        | $3 : 1$        | $1 : 1$        |
| $1 : 1$        | $2 : 1$        | $1 : 1$        |
| $2 : 1$        | $1 : 1$        | $1 : 1$        |
| $1 : 1$        | $3 : 1$        | $1 : 1$        |
| $1 : 1$        | $2 : 1$        | $1 : 1$        |
rate is expected. The effective mass for neutrinoless double beta decay experiments is given by

$$\langle m_{\text{eff}} \rangle = \frac{1}{2} \sum_{j} U_{e j}^2 \left( m_{j}^+ - m_{j}^- \right) = \frac{1}{2} \sum_{j} U_{e j}^2 \frac{\delta m_j^2}{2m_j}$$  \hspace{1cm} (10)$$

which is unmeasurably small, $\langle m_{\text{eff}} \rangle \lesssim 10^{-4}$ eV for the inverted hierarchy and even less for the normal hierarchy. In contrast, in the mirror model \cite{4}, the sum above has $(m_{j}^+ + m_{j}^-)$, and can thus produce an observable signal.

**Cosmology with Neutrinos.**— It is fascinating that non-averaged oscillation phases, $\delta \phi_j = \delta m_j^2 t / 4p$, and hence the factors $\chi_j$, are rich in cosmological information \cite{10}. Integrating the phase backwards in propagation time, with the momentum blue-shifted, one obtains

$$\delta \phi_j = \int_{0}^{z_e} dz \frac{dt}{4p_0(1+z)} \frac{\delta m_j^2}{4p_0}$$

$$= \left( \frac{\delta m_j^2 H_0^{-1}}{4p_0} \right) \int_{1}^{1+z_e} d\omega \omega^2 \sqrt{\omega^3 \Omega_m + (1 - \Omega_m)}$$

where $z_e$ is the red-shift of the emitting source, and $H_0^{-1}$ is the Hubble time, known to 10\% \cite{15}. This result holds for a flat universe, where $\Omega_m + \Omega_\Lambda = 1$, with $\Omega_m$ and $\Omega_\Lambda$ the matter and vacuum energy densities in units of the critical density. The integral is the fraction of the Hubble time available for neutrino transit. For the presently preferred values $\Omega_m = 0.3$ and $\Omega_\Lambda = 0.7$, the asymptotic ($z_e \to \infty$) value of the integral is 0.53. This limit is approached rapidly: at $z_e = 1 \pm 2$ the integral is 77\% (91\%) saturated. For cosmologically distant ($z_e > 1$) sources such as gamma-ray bursts, non-averaged oscillation data would, in principle, allow one to deduce $\delta m_j^2$ to about 20\%, without even knowing the source red-shifts. Known values of $\Omega_m$ and $\Omega_\Lambda$ might allow one to infer the source redshifts $z_e$, or vice-versa.

Such a scenario would be the first measurement of a cosmological parameter with particles other than photons. An advantage of measuring cosmological parameters with neutrinos is the fact that flavor mixing is a microscopic phenomenon and hence presumably free of ambiguities such as source evolution or standard candle assumptions \cite{10,19}. Another method of measuring cosmological parameters with neutrinos is given in Ref. \cite{20}.

**Conclusions.**— Neutrino telescope measurements of neutrino flavor ratios may achieve a sensitivity to mass-squared differences as small as $10^{-18}$ eV$^2$. This can be used to probe possible tiny pseudo-Dirac splittings of each generation, and thus reveal Majorana mass terms (and lepton number violation) not discernable via any other means.

**Note added:** As this work was being finalized, a paper appeared which addresses some of the issues herein \cite{21}.
