The $tW^-$ Mode of Single Top Production

Tim M. P. Tait

Abstract

The $tW^-$ mode of single top production is proposed as an important means to study the weak interactions of the top quark. While the rate of this mode is most likely too small to be observed at Run II of the Fermilab Tevatron, it is expected to be considerably larger at the CERN LHC. In this article the inclusive $tW^-$ rate is computed, including $\mathcal{O}(1/\log m_t^2/m_W^2)$ corrections, and when combined with detailed Monte Carlo simulations including the top and $W$ decay products, indicate that the $tW^-$ single top process may be extracted from the considerable $t\bar{t}$ and $W^+W^-j$ backgrounds at low luminosity runs of the LHC.

1 Introduction

The discovery of the top quark at the Fermilab Tevatron [1] completes the fermionic sector of the Standard Model (SM) of particle physics. However, many questions regarding the top remain, and require further investigation to be settled. The primary question is whether or not the top is “just another quark”, or if its large mass is indicative that it is something more. The top’s enormous mass may be a clue that it plays a special role in the Electroweak symmetry breaking (EWSB), and many of the proposed extensions of the SM explain the large top mass by allowing the top to participate in modified or nonstandard dynamics [2], connected to the physics which provides the mass of the $W$ and $Z$ bosons. This intriguing hypothesis is best explored by careful study of top observables. In particular, single top production, as a measure of the top quark’s electroweak interactions, is an excellent place to look for new physics related to the EWSB [3].

Single top production proceeds through three distinct modes at a hadron collider. The choice of the word “mode”, as opposed to “sub-process” is motivated by the fact that each process has different initial and final states, and thus they are in principle separably measurable. The $t$-channel $W$-gluon fusion mode [4, 5, 6, 7] involves the exchange of a space-like $W$ boson between a light quark, and a bottom ($b$) quark inside the incident hadrons, resulting in a jet and a single top quark. Its rate is rather large at both the Tevatron and the LHC. The $s$-channel $W^*$ mode [8] involves production of an off-shell, time-like $W$ boson, which then decays into a top and a bottom quark. It has a relatively large rate at the Tevatron, but is comparatively small at the LHC because it is driven by initial state anti-quark parton densities. Finally, the $t W^-$ mode of single top production involves an initial state $b$ quark emitting a (close to) on-shell $W^-$ boson, resulting in a $t W^-$ final state. Because of the massive particles in the final state, this mode has an extremely small rate at the Tevatron, but is considerable at the LHC where more partonic energy is available.

Each mode has rather distinct event kinematics, and thus are potentially observable separately from each other [6]. In fact it has been shown [3, 9] that each mode is sensitive to different types of new physics, with the $t W^-$ mode distinct in that it is sensitive only to physics which directly modifies the $W$-$t$-$b$ interaction from its SM structure. This distinction is a result of the fact that in this mode both the top and the $W$ are directly observable, whereas in the other two modes the $W$ bosons are virtual, and thus those processes may receive contributions from exotic types of charged bosons or FCNC operators involving the top. Even without invoking additional particles or FCNC interactions, the three modes provide complimentary information about the $W$-$t$-$b$ interaction by probing it in different regions of momentum transfer. The $t$-channel and $s$-channel processes study the vertex when the $W$ boson is space-like or time-like, respectively, and the fermions are (approximately) on-shell. The $t W^-$ mode involves the interaction when the $W$ boson is on-shell, and one of the fermion lines is off-shell. These considerations are compelling reasons to examine the three modes of single top separately, to extract the maximum
This article contains a detailed study of the $tW^-$ mode of single top production with the intent to observe this process for its own sake. Previous analyses focused on this process as a background to heavy Higgs decays ($h \rightarrow W^+W^-$) [10] or combined all three single top modes together into one signal [11, 12]. For the reasons stated above, it is also very important to study the $tW^-$ mode independently from the other single top processes. The presentation is arranged as follows. In Section 2, the inclusive $tW^-$ rate is computed, including large logarithmic corrections of $\mathcal{O}(1/\log m_t^2/m_h^2)$. In Section 3, a Monte Carlo simulation of the signal and the major backgrounds is discussed for the LHC collider, and it is demonstrated that the $tW^-$ signal may be observed with about 1 fb$^{-1}$ of collected data. A summary of the results are given in Section 4. Finally, the helicity amplitudes for the signal process at leading order (LO), including all decays are presented in the appendix.

2 The inclusive $tW^-$ Rate

2.1 Leading Order $2 \rightarrow 2$ Contributions

Before turning to the details of how the $tW^-$ process may be observed against the background, it is necessary to discuss the inclusive rate of this process at a hadron collider. As is the case with the $t$-channel single top mode [4], the $tW^-$ rate involves finding a $b$ quark inside one of the incident (anti-) protons. The underlying picture is actually that a gluon ($g$) in one of the protons splits into a $b\bar{b}$ pair, with one of these bottom quarks taking part in the hard scattering, as is shown in Figure 1. In order to facilitate the discussion below, only $tW^-$ production will be considered, and not $\bar{t}W^+$ production. It should be clear how the remarks on single top production may also be applied to single anti-top production with an appropriate switch of $b \leftrightarrow \bar{b}$, $t \leftrightarrow \bar{t}$, and $W^\pm \leftrightarrow W^\mp$.

One could imagine computing the inclusive $tW^-$ rate from a gluon-gluon initial state,
Figure 2: Feynman diagrams for the $tW^-$ mode of single top production after resumming large logarithms into a gluon PDF: $gb \rightarrow tW^-$. Such as the one shown in Figure 1. However, this picture results in a perturbative expansion that is spoiled by the kinematic region in which the produced $b$ quark is approximately collinear with the incoming gluon, which produces a contribution containing large logarithms of the form $\alpha_S \log (m_t^2/m_b^2)$, which for $m_t \sim 175$ GeV, $m_b \sim 5$ GeV, and $\alpha_S \sim 0.1$ is over-all of order 1. In fact, the $n$th order correction to the process always contains a collinear piece which behaves as $(\alpha_S \log (m_t^2/m_b^2))^n$, spoiling the perturbative description.

A convergent perturbative expansion is restored by resumming these logarithms into a bottom quark parton distribution function (PDF) [13], which is unlike the usual light parton PDF’s in that it is perturbatively derived from the gluon distribution function. Thus, the LO contribution to inclusive $tW^-$ production is best considered to arise from Feynman diagrams such as those shown in Figure 2, which treat the bottom quark as a parton.

This reordering of the perturbation series improves its convergence, and allows accurate estimation of the inclusive cross section. In fact, this two particle to two particle ($2 \rightarrow 2$) description also represents the most important part of the $tW^-$ kinematics, because the dominant kinematic configuration is one in which the $b$ is collinear with its parent gluon [3]. However, since it effectively integrates out the $b$ momentum, and approximates it as collinear with the parent hadron, this $2 \rightarrow 2$ process does not accurately describe the situation when the $b$ has large transverse momentum ($p_T$). In this region, a description based on the original $2 \rightarrow 3$ process is more appropriate, and since this is the situation in which the $b$ is not collinear with the incoming gluon, it is well defined in perturbation theory. Thus, we will see that while it is not possible to compute kinematic distributions in the region in which the $p_T$ of the $b$ is small using standard perturbation theory, it is possible to compute the inclusive rate for the process with $p_T^b > p_T^{cut}$, so long as $p_T^{cut}$ is chosen large enough that the perturbative description remains valid.

\[1\] The helicity amplitudes for this $2 \rightarrow 2$ contribution, including the top and $W$ decays, can be found in Appendix A.
2.2 $\mathcal{O}(1/\log m_t^2/m_b^2) \ 2 \to 3$ Corrections

Though the complete next-to-leading order (NLO) QCD corrections are still underway, the prediction for the inclusive $tW^-$ rate may be improved over the LO result by including the $\mathcal{O}(1/\log m_t^2/m_b^2)$ corrections coming from Feynman diagrams such as those in Figure 3. These diagrams may be separated into three classes. Figure 3a contains a representative diagram which contains the collinear $\mathcal{O}(1/\log m_t^2/m_b^2)$ behavior under study. Figure 3b corresponds to a class of corrections that include contributions which look like $t\bar{t}$ production followed by the decay $\bar{t} \to W^- b$. The diagram of Figure 3c contains a separate $\mathcal{O}(\alpha_S)$ correction that involves neither potentially on-shell $\bar{t}$ quarks nor large logarithms.

There are two subtle points that must be carefully dealt with when including these corrections. The first is that when the $b$ PDF was defined, the collinear contributions from these diagrams were already resummed into what we called the LO contribution. Thus, in order to avoid double-counting this collinear region one must subtract out this portion. This may be expressed by writing the full cross section for $AB \to tW^-$ as,

$$\sigma_{tW} = \sigma^0(AB \to t W^-) + \sigma^1(AB \to t W^- b) - \sigma^S(AB \to t W^- b), \quad (1)$$

with the individual terms given by,

$$\sigma^0(AB \to t W^-) = \int dx_1 dx_2 \{ f_{g/A}(x_1, \mu) f_{b/B}(x_2, \mu) \sigma(b g \to t W^-)$$

$$+ f_{b/A}(x_1, \mu) f_{g/B}(x_2, \mu) \sigma(g b \to t W^-) \} \quad (2)$$

$$\sigma^1(AB \to t W^- b) = \int dx_1 dx_2 f_{g/A}(x_1, \mu) f_{g/B}(x_2, \mu) \sigma(g g \to t W^- b)$$

$$\sigma^S(AB \to t W^- b) = \int dx_1 dx_2 \left\{ \tilde{f}_{b/A}(x_1, \mu) f_{g/B}(x_2, \mu) \sigma(b g \to t W^-)$$

$$+ f_{g/A}(x_1, \mu) \tilde{f}_{b/B}(x_2, \mu) \sigma(g b \to t W^-) \right\},$$

where $f_{i/H}(x, \mu)$ represents the parton distribution function for parton $i$ carrying momentum fraction $x$ at scale $\mu$ to be found in hadron $H$. The “modified $b$ PDF”, $\tilde{f}_{b/H}$, contains the collinear logarithm and splitting function $P_{b\to g}$ convoluted with the gluon PDF,

$$\tilde{f}_{b/H}(x, \mu) = \frac{\alpha_S(\mu)}{2 \pi} \log \left( \frac{\mu^2}{m_b^2} \right) \int_x^1 \frac{dz}{z} \left[ \frac{z^2 + (1-z)^2}{2} \right] f_{g/H} \left( \frac{x}{z}, \mu \right). \quad (3)$$

By including this term, the collinear behavior in $\sigma^1(AB \to t W^-)$, which was already implicitly included in $\sigma^0(AB \to t W^-)$, is removed. Thus, the problem of double-counting the collinear region is resolved.

\footnote{This result is derived by including a small (but non-zero) bottom mass in the $2 \to 3$ matrix elements in order to regulate the collinear divergence occurring in the class of diagrams represented by Figure 3a.}
Figure 3: Representative Feynman diagrams for corrections to the $tW^-$ mode of single top production corresponding to (a) large log corrections associated with the $b$ PDF, (b) LO $t\bar{t}$ production followed by the LO decay $\bar{t} \to W^- b$, and (c) pure $\alpha_S$ corrections.

The second subtle point in evaluating the large log contributions is that they contain contributions such as those found in Figure 3b that correspond to LO $gg \to t\bar{t}$ production followed by the LO decay $\bar{t} \to W^- b$. This expresses the fact that as one considers higher orders in perturbation theory, the distinction between $t\bar{t}$ production and various types of single top production is blurred. However, when considering quantities that are properly defined, these corrections are small, and there is no problem distinguishing these processes. As a matter of book keeping, the corrections to $tW^-$ production involving an on-shell $\bar{t}$ are more intuitively considered a part of the LO $t\bar{t}$ rate, and thus it is important to subtract them out to avoid double counting in this kinematic region. This may be done by noting that in the region where the invariant mass of the $\bar{b}W^-$ system, $M_{\bar{b}W^-}$, is close to the top mass, the behavior of the partonic cross section $\sigma(gg \to tW^- b)$ may be expressed,

$$\frac{d\sigma}{dM_{\bar{b}W^-}}(gg \to tW^- b) = \sigma^{LO}(gg \to t\bar{t}) - \sigma^{LO}(gg \to t\bar{t}) \frac{m_t \Gamma^{LO}(\bar{t} \to W^- b)}{\pi [(M_{\bar{b}W^-}^2 - m_t^2)^2 + m_t^2 \Gamma_t^2]}$$

where $\sigma^{LO}(gg \to t\bar{t})$ and $\Gamma^{LO}(\bar{t} \to W^- b)$ are the LO cross section and partial width, $\Gamma_t$ is the inclusive top decay width, and $BR$ denotes the branching ratio. The last distribution identity holds in the limit $\Gamma_t \ll m_t$. Having identified this LO on-shell piece, it may now be simply subtracted from $\sigma(gg \to tW^- b)$. The advantage to this formulation of the subtraction is that by taking the narrow width limit, one removes all of the on-shell $\bar{t}$ contribution. The interference terms between one of the on-shell $\bar{t}$ amplitudes and an amplitude without an on-shell $\bar{t}$ involve a Breit-Wigner propagator of the form, $(M_{\bar{b}W^-}^2 - m_t^2 + i m_t \Gamma_t)^{-1}$, which in the limit of small $\Gamma_t$, may be expressed as a principle valued integral in $M_{\bar{b}W^-}$. Following this prescription, and choosing a canonical scale choice of $\mu_0 = \sqrt{s}$, where $s$ is the invariant mass of the incoming partons, leads to a large log correction to the $tW^-$ rate of $-9.5\%$ at the LHC, which is consistent with previous
experience from the $W$-gluon fusion mode of single top production [1].

This problem of the on-shell top was dealt with another way in [12], where a cut was applied on $M_{Wb}$ to exclude the region of $|M_{Wb} - m_t| \leq 3 \Gamma_t$. Following this prescription, one finds a much larger correction of about +50% to the $t W^-$ rate at the LHC. However, this is misleading because the large corrections are mostly coming from the region where the $\bar{t}$ is close to on-shell (though still at least 3 top widths away). In other words, the large positive correction comes from the tails of the Breit-Wigner distribution for on-shell $\bar{t}$ production. This can be simply understood by taking the prescription in [12] and varying the cut by increasing the interval about the on-shell $\bar{t}$ region that is excluded. One finds that the correction computed in this way varies quite strongly with the cut, and reproduces the subtraction method we have employed for the cut $|M_{Wb} - m_t| \leq 12 \Gamma_t$. A theoretical advantage of the subtraction method employed here is that when one determines the $t \bar{t}$ and $t W^-$ rates, one would like to actually fit the data to the sum of the two rates, and thus the subtraction method allows one to simply separate this sum into the two contributions without introducing an arbitrary cut-off into the definition of the separation.

Even if one were to use a cut-off to effect the separation, there is a further problem in employing the cut $|M_{Wb} - m_t| \leq 3 \Gamma_t$ to remove on-shell $t \bar{t}$ production. This is that from a purely practical point of view $3 \Gamma_t \sim 4.5$ GeV, which is much smaller than the expected jet resolution at the Tevatron or LHC. Thus, it is not experimentally possible to impose this definition of the separation between $t W^-$ and $t \bar{t}$. A more realistic resolution is about 15 GeV [14], which corresponds to a subtraction of $|M_{Wb} - m_t| \leq 10 \Gamma_t$. As we have seen above, this choice of the $M_{Wb}$ cut agrees rather well with our subtraction method result.

In Tables 1 and 2 can be found the LO rate (including the large log corrections described above) of $t W^-$ production at the Tevatron and LHC, for various choices of $m_t$, the CTEQ4L [15] and MRRS(R1) [16] PDF’s, and 3 choices of factorization scale, with the canonical scale choice set to $\mu_0 = \sqrt{s}$. These results assume $V_{tb} = 1$, $V_{ts}, V_{td} = 0$ and no decay branching ratios are included. At both Tevatron and LHC, the rate for $t W^+$ production is equal to the rate of $t W^-$ production, and thus the sum of the two rates may be obtained by multiplying the cross sections by two. From these results, we see that varying the scale by a factor of two produces a variation in the resulting cross section of about ±25% at the Tevatron and ±15% at the LHC. This large scale dependence signals the utility in having a full NLO ($\alpha_s$) computation of this process in order to have a more theoretically reliable estimate for the cross section.

It is further interesting to examine the dependence of the result on the choice of PDF, as the $t W^-$ process is sensitive to the gluon density, which is parameterized differently by the CTEQ4 and MRRS PDF’s. This provides one with an estimate of the the uncertainty due to the difference in PDF parameterization. Unlike the light quark distributions, which are rather well determined by deeply inelastic scattering (DIS) data, the gluon PDF is relatively poorly known at large momentum fraction, and thus the two parameterizations can lead to rather different results for the $t W^-$ cross section. For $m_t = 175$ GeV,

\[ V_{ts} \text{ and } V_{td} \] have a negligible effect on the cross section, because these parameters are required by low energy processes to be extremely small [17].

\[ ^3 \text{The inclusion of non-zero } V_{ts} \text{ and } V_{td} \] have a negligible effect on the cross section, because these parameters are required by low energy processes to be extremely small [17].

comparing at the canonical scale choice, a variation of $\pm 6\%$ at the Tevatron and $\pm 8\%$ at the LHC results when moving from either the CTEQ4L or MRRS(R1) result to the mean of the two. However, care must be taken in drawing firm conclusions from this because these two sets of PDF's are extracted from a very similar collection of experimental data. Thus, this estimate does not accurately reflect the uncertainty in the PDF’s coming from the uncertainties in the data from which they are derived.

Table 2: The LO (with $O(1/\log(m_t^2/m_b^2)$ corrections) rates for $b g \to t W^-$ (in pb) at the LHC. The rate of $\bar{t}$ production is equal to the rate of $t$ production.
3 Extracting $tW^-$ from the Background

In this section we present the results of a Monte Carlo study illustrating how one may extract the $tW^-$ signal from the relatively large backgrounds. A top mass of $m_t = 175$ GeV is assumed. The $tW^-$ signature consists of the decay products of an on-shell top quark and $W^-$ boson. The SM top decay is $t \rightarrow W^+ b$, and the $W$ bosons may decay either into quarks or leptons. While the hadronic $W$ decays are dominant (with branching ratio $6/9$), the leptonic decays are generally cleaner, and energetic leptons provide an excellent trigger at a hadron collider. Thus, it is necessary to consider at least one of the $W$ bosons decaying into leptons. This study will be confined to the case where both $W$'s decay into leptons, $W \rightarrow \ell \nu$ with $\ell = e, \mu$. This avoids potentially huge QCD backgrounds involving production of one $W$ boson and two or more jets whose invariant mass happens to lie close to $m_W$. Thus, the signature contains two relatively hard charged leptons, missing transverse energy ($\not\!p_T$) from the unobserved neutrinos, and a bottom quark from the single top decay.

The primary background comes from processes which contain two weak bosons and a bottom quark. This includes partonic processes such as continuum $W^+ W^- b$ (shown in Figure 4) which involve off-shell top exchange. In fact, this process is interesting in its own right as a further test of the $W$-$t$-$b$ interaction. However, the lack of an on-shell top quark will make this process quite difficult to distinguish from the backgrounds. There are also important fake backgrounds from processes that are similar to the $tW^-$ process, and may be misidentified as such. This includes $t\bar{t}$ production, when one of the bottom quarks from a top decay is unobserved because it falls outside of the detector coverage. As the inclusive $t\bar{t}$ rate is more than an order of magnitude larger than the inclusive $tW^-$ rate, this is potentially a serious problem in discovering the $tW^-$ process. Another class of potentially important backgrounds is $W^+ W^- j$ production (where $j$ is a light quark or a gluon) which are problematic because of the small but non-zero probability that $j$ may be misidentified as jet containing a bottom quark. It should be noted that this set of backgrounds also includes $ZZj$ production, with one $Z$ decaying into charged leptons, and the other into

Figure 4: Illustrative Feynman diagram for the irreducible background, $W^+ W^- b$ production, involving an off-shell top quark. The leptonic decay modes of the $W$ bosons are not indicated here.
In order to be considered observable, the charged leptons and $b$ jet are required to have $p_T \geq 15$ GeV, and to lie in the central region of the detector, with rapidity $|\eta| \leq 2$. In order to be resolvable as distinct objects, the charged lepton and jet are required to have a cone separation $\Delta R \geq 0.4$, where $\Delta R = \sqrt{\Delta \eta^2 + \Delta \phi^2}$, with $\Delta \phi$ the separation in the azimuthal angle, and $\Delta \eta$ the difference in pseudorapidity. In the second column of Table 3, we can find the number of events passing these cuts for signal and backgrounds at the LHC, assuming $20 \text{ fb}^{-1}$ of integrated luminosity.

In order to suppress the large $t \bar{t}$ background, it is desirable to exclude events with more than one $b$ quark at high transverse momentum. The estimation of the effect of this cut on the $tW^-$ signal is somewhat delicate, because, as was discussed in Section 2, the kinematics of the $\bar{b}$ in the signal events are not calculable in usual formulation of perturbative QCD. However, the effect of the cut may nonetheless be computed using a technique developed for the $W$-gluon fusion process [7]. The inclusive $tW^-$ rate computed

---

Table 3: The number of signal $tW^-$ events as well as the major backgrounds, for $20 \text{ fb}^{-1}$ of integrated luminosity at the LHC after applying cuts described in the text.

| Process       | Acceptance Cuts | $p_T^* \leq 15$ GeV | $b$-tagging |
|---------------|-----------------|---------------------|-------------|
| $tW^-$        | 25250           | 13535               | 8121        |
| $W^+W^-b$     | 114             | 114                 | 68          |
| $W^+W^-j$     | 2460            | 2460                | 25          |
| $t\bar{t}$    | 270495          | 15074               | 9044        |

neutrinos. As we shall see, the $W^+W^- j$ and $W^+W^- b$ backgrounds are much smaller than either the $tW^-$ signal or the $t\bar{t}$ background. This is easily understood from the fact that the $W^+W^- b$ and $W^+W^- j$ backgrounds are $2 \to 3$ production processes of $O(\alpha_s \alpha_W)$ (followed by $W$ decays), whereas the signal and $t\bar{t}$ background are $2 \to 2$ production processes of $O(\alpha_s \alpha_W)$ and $O(\alpha_s^2)$ respectively, followed by top decays with unit branching ratio and the same $W$ decays.

The $tW^-$ signal, $W^+W^- b$, and $W^+W^- j$ backgrounds are simulated at the parton level, at LO in the strong and weak couplings. The matrix elements for the $tW^-$ process, including all of the decays have been computed at the helicity amplitude level, and are presented in Appendix A. Matrix elements for the $W^+W^- b$ and $W^+W^- j$ processes have been obtained from the MADGRAPH code [18]. The $t\bar{t}$ background is simulated at LO, using the ONETOP code [19]. For all processes, a scale choice of the partonic energy, $\mu = \sqrt{s}$ is chosen, and the CTEQ4L PDF is used with LO running of the strong coupling $\alpha_s$. Though NLO results for $t\bar{t}$ production are currently available [20], we use the LO rates in order to make a fair comparison between this background, the signal, and the other backgrounds, for which NLO results are currently unknown.

In order to be considered observable, the charged leptons and $b$ jet are required to have $p_T \geq 15$ GeV, and to lie in the central region of the detector, with rapidity $|\eta| \leq 2$. In order to be resolvable as distinct objects, the charged lepton and jet are required to have a cone separation $\Delta R \geq 0.4$, where $\Delta R = \sqrt{\Delta \eta^2 + \Delta \phi^2}$, with $\Delta \phi$ the separation in the azimuthal angle, and $\Delta \eta$ the difference in pseudorapidity. In the second column of Table 3, we can find the number of events passing these cuts for signal and backgrounds at the LHC, assuming $20 \text{ fb}^{-1}$ of integrated luminosity.

In order to suppress the large $t\bar{t}$ background, it is desirable to exclude events with more than one $b$ quark at high transverse momentum. The estimation of the effect of this cut on the $tW^-$ signal is somewhat delicate, because, as was discussed in Section 2, the kinematics of the $\bar{b}$ in the signal events are not calculable in usual formulation of perturbative QCD. However, the effect of the cut may nonetheless be computed using a technique developed for the $W$-gluon fusion process [7]. The inclusive $tW^-$ rate computed

---

4The $\Lambda_{QCD}$ with 5 active flavors appropriate for the CTEQ4L fit is 181 MeV.
in Section 2 represents the $tW^-$ rate summed over all $p_T$ of the $\bar{b}$. Further, one can use the $2 \to 3$ description with a sufficiently strong cut on the $p_T$ of the $\bar{b}$ to reliably obtain the cross section when the $\bar{b}$ has a large transverse momentum. Since the inclusive rate is equal to the sum of the rate below the $p_T$ cut and the rate above the $p_T$ cut, one thus computes the signal cross section below the $p_T$ cut from,

$$\sigma_{tW^-}(p_T^{\bar{b}} \leq p_T^{cut}) = \sigma_{tW^-}^{inclusive} - \sigma_{tW^-}(p_T^{\bar{b}} \geq p_T^{cut}).$$  

(5)

The effect of the cut $p_T^{\bar{b}} \leq 15$ GeV on the signal and backgrounds is shown in the third column of Table 5. As is indicated, this cut is extremely effective at suppressing the $t\bar{t}$ background, drastically reducing it by about 94%, while eliminating only about 47% of the signal rate.

The $W^+W^-$ jet background has been simulated using the exact matrix elements for $q\bar{q} \to W^+W^- g$ and $qg \to W^+W^- q$, which is appropriate for high energy jets. However, it is expected that this background may receive further contributions from initial and final state showering, and fragmentation, which have not been included in our estimate. Thus, in order to be conservative, we include $b$-tagging in our search to select events containing a bottom quark. The $b$-tagging efficiency is estimated by assuming a 60% probability of correctly identifying a bottom quark passing the acceptance cuts described above. The probability of mis-tagging a light quark or gluon is assumed to be 1%. The effect of this requirement is indicated in the final column of Table 5.

One may now estimate the ability of the LHC to study the $tW^-$ process. The significance of the signal over the background is defined as the number of signal events divided by the square-root of the number of background events. As the total number of events satisfying our search criterion is large, this approximation based on Gaussian statistics is justified. From the final column of Table 5, the significance at the LHC with 20 fb$^{-1}$ of integrated luminosity is seen to be 84.9, indicating that even with a relatively small amount of data the LHC will be able to identify the signal from the background. An alternative presentation is that the LHC will observe the $tW^-$ mode of single top production at the 5$\sigma$ level with less than 1 fb$^{-1}$ of data. In comparison, at the Tevatron Run II with 2 fb$^{-1}$, it is found that after applying the acceptance and $p_T^{\bar{b}}$ cuts, the signal rate is expected to be slightly less than 1 event, thus indicating that another search strategy must be employed in order to observe $tW^-$ at the Tevatron.

---

5Since this cut restricts the $p_T$ of the $\bar{b}$ to be small, we continue to simulate the signal rate from the $2 \to 2$ process (followed by decays) described in the Appendix, which makes the approximation $p_T^{\bar{b}} = 0$.

6The probability of misidentifying a charm quark as a bottom is closer to 15%. However, as the $W^+W^- c$ portion of the already small $W^+W^- j$ background is only about 7%, this is of negligible significance.
4 Conclusions

This article is the first proposal to separately study the $tW^-$ mode of single top production for its own sake. The inclusive rate has been computed, including the large log corrections from the definition of the bottom quark PDF. This procedure requires some attention because of potential problems with double-counting both the region where the $\bar{b}$ quark is collinear with the incident gluon, and with $t\bar{t}$ production. After appropriate subtractions, the corrections to the $tW^-$ rate are determined, and it is found that the net correction is about $-10\%$ at the LHC.

A full parton-level event simulation has been completed at the LHC, including the decay products from the top and $W$ bosons. The decay mode in which both $W$ bosons decay into leptons has been identified as a signature with a relatively small QCD jet background, though other decay modes are also potentially interesting. The $t\bar{t}$ rate is found to be a serious background, but it may be reduced by applying simple cuts to extract the signal from the background. After applying these cuts, it is found that a $5\sigma$ observation of the $tW^-$ signal is possible at very low luminosities at the LHC. Turning this around, one finds a statistical error of about $1\%$ in the measured cross section at the LHC with $20$ fb$^{-1}$. This error is much smaller than the theoretical uncertainty of $\pm15\%$ from the scale dependence, which motivates further work to include higher orders of perturbation theory in the $tW^-$ rate.

If the top quark has indeed been given a special role in the generation of masses, it is crucial that its interactions be carefully studied in order to learn what properties the underlying theory at high energies must possess. The deviations of the top interactions from the SM predictions may represent the best clues on the nature of the EWSB. The $tW^-$ rate of single top production represents an opportunity to learn about the top quark’s weak interactions from a different perspective than is afforded by the $W$-gluon fusion and $W^*$ modes, both because the top and $W$ are observed, thus allowing one to study the $W$-$t$-$b$ coupling independently from the possibility of FCNC and heavy particles, and also to probe the $W$-$t$-$b$ interaction in a different region of momentum transfer from the other two channels. It thus represents an essential means to determine the properties of the top quark.

A Helicity amplitudes for \( bg \to t W^- \to b e^+ \nu_e \mu^- \bar{\nu}_\mu \)

In this appendix, the helicity amplitudes for the \( t W^- \) process are presented, including the decay products of the \( t \) and \( W \). The helicity amplitudes for the other modes of single top production, as well as the \( t \bar{t} \) background, may be found in [5]. Our conventions for implementing the helicity amplitudes may be found in Appendix A of that work, and are embodied in the two-component ket notation for the spinors,

\[
|p_i+> = \sqrt{2E_i} \left( \begin{array}{c} \cos \theta/2 \\ e^{i\phi} \sin \theta/2 \end{array} \right), \quad |p_i-> = \sqrt{2E_i} \left( \begin{array}{c} -e^{i\phi} \sin \theta/2 \\ \cos \theta/2 \end{array} \right)
\]

where \( E_i, \theta, \) and \( \phi \) refer to the energy, polar angle, and azimuthal angles of four-momentum \( p_i \). A further notational convenience is to introduce \( 2 \times 2 \) Dirac matrices \( \gamma^\pm_\mu = (1, \pm \vec{\sigma}) \), from which follows the “slash” notation \( \hat{p}^\pm = p^\mu \gamma^\pm_\mu \). Particle momenta are indicated by the hatted particle label, i.e., \( p_{e^+} = \hat{e}^+ \).

Purely for the purposes of labelling, we distinguish the decay products of the \( W^- \) boson from the \( W^+ \) boson by assuming the decays,

\[
W^- \to \mu^- \bar{\nu}_\mu, \quad t \to b W^+; \quad W^+ \to e^+ \nu_e.
\]

The other modes of the \( W \) decays may be easily obtained from this choice by including the appropriate sum over colors for each set of \( W \) decay products in the final (cross section) result. Namely, each hadronic \( W \) decay into quarks multiplies the cross section by \( N_C = 3 \) compared to the leptonic modes presented here.

The results do not include the (negligible) masses of any fermions other than the top. This assumption of massless fermions has a profound effect on the helicity structure of the matrix elements because of the left-chiral structure of the \( W \) interaction. The net result is that only the particular helicity structure \( \lambda_{b^f} = -1, \lambda_{\mu^-} = -1, \lambda_{\nu_e} = +1, \lambda_{e^+} = +1, \lambda_{\nu_e} = -1, \lambda_{b^f} = -1 \) has a non-zero contribution, where \( \lambda_n = \pm 1 \) when the spin polarization of particle \( n \) is along (against) its direction of motion. \( b^f \) denotes the initial state \( b \) quark, while \( b^{f'} \) denotes the final \( b \) resulting from the \( t \) decay. The only remaining polarization to be specified is that of the initial gluon. Denoting the initial gluon spin as...
expressed according to the Breit-Wigner prescription. The propagators for the (approximately) on-shell 
N \pm \frac{1}{2} for right (left) handed gluons, the two amplitudes may be expressed as,

\[ M_1(\pm) = \left( \frac{\sqrt{2} g_s^2 g_s(2E_g)^{-1}}{(i_1^2 - m_1^2)(W_1^2 - m_1^2 + im_1 \Gamma_1)(i_2^2 - m_2^2 + im_2 \Gamma_2)} \right) \times < \hat{b}^f - | \hat{\nu}_e + > < \hat{\nu}_\mu + | \hat{b}^i - > \times (m_1^2 < \hat{e}^+ + | \hat{g}^+ > < \hat{g} - | \hat{\mu}^- + > - < \hat{e}^+ + | \hat{f}_2^- | \hat{g}^+ > < \hat{g} - | \hat{f}_1^- | \hat{\mu}^- + > ) \]

\[ M_2(\pm) = \left( \frac{\sqrt{2} g_s^2 g_s(2E_g)^{-1}}{(i_1^2 - m_1^2)(W_1^2 - m_1^2 + im_1 \Gamma_1)(i_2^2 - m_2^2 + im_2 \Gamma_2)} \right) \times < \hat{b}^f - | \hat{\nu}_e + > < \hat{\nu}_\mu + | \hat{b}^i - > \times (m_1^2 < \hat{e}^+ + | \hat{g}^- > < \hat{g} + | \hat{\mu}^- + > - < \hat{e}^+ + | \hat{f}_2^- | \hat{g}^- > < \hat{g} + | \hat{f}_1^- | \hat{\mu}^- + > ) \]

\[ M_2(\pm) = \left( \frac{\sqrt{2} g_s^2 g_s(2E_g)^{-1}}{(i_1^2 - m_1^2)(W_1^2 - m_1^2 + im_1 \Gamma_1)(i_2^2 - m_2^2 + im_2 \Gamma_2)} \right) \times < \hat{b}^f - | \hat{\nu}_e + > < \hat{\nu}_\mu + | \hat{b}^i - > \times (m_1^2 < \hat{e}^+ + | \hat{g}^- > < \hat{g} + | \hat{\mu}^- + > - < \hat{e}^+ + | \hat{f}_2^- | \hat{g}^- > < \hat{g} + | \hat{f}_1^- | \hat{\mu}^- + > ) \]

where,

\[ \hat{W}_1 = \hat{e}^+ + \hat{\nu}_e, \]
\[ \hat{W}_2 = \hat{\mu}^- + \hat{\nu}_\mu, \]
\[ \hat{t}_1 = \hat{b}^i - \hat{W}_1, \]
\[ \hat{t}_2 = \hat{b}^i + \hat{W}_1, \]
\[ \hat{b}_1 = \hat{b}^i + \hat{g}, \]

and \( E_g \) is the gluon energy, \( g_s \) is the strong coupling constant, and \( g_W = e / \sin \theta_W \) is the weak coupling. The matrix elements squared, \( |M|^2 \), should be summed over final colors and averaged over initial colors, resulting in a factor of 1/6, and averaged over initial spins, giving a further factor of 1/4. As was noted above, this color factor reflects the case where both W bosons decay into leptons. A W decay into quarks further multiplies the cross section by \( N_C = 3 \) for one hadronic W decay, and \( N_C^2 = 9 \) if both W’s decay into hadrons. The propagators for the (approximately) on-shell \( W^\pm \) and top have been expressed according to the Breit-Wigner prescription.
