(Received 6 June 2004; revised manuscript received 5 October 2004; published 7 February 2005)

We present a dynamic van der Waals theory. It is useful to study phase separation when the temperature varies in space. We show that, if heat flow is applied to liquid suspending a gas droplet at zero gravity, a convective flow occurs such that the temperature gradient within the droplet nearly vanishes. As the heat flux is increased, the droplet becomes attached to the heated wall that is wetted by liquid in equilibrium. In one case corresponding to partial wetting by gas, an apparent contact angle can be defined. In the other case with larger heat flux, the droplet completely wets the heated wall expelling liquid.

In the usual theories of phase transitions, the fluctuations of the temperature $T$ are assumed to be small and are neglected. However, there can be situations in which phase transitions occur in inhomogeneous $T$. For example, wetting properties near the gas-liquid critical point are very sensitive to applied heat flux [1,2], and boiling processes remain largely unexplored [3,4]. To treat such problems we propose to start with coarse-grained entropy and energy, from which the temperature is defined as a functional of the order parameter and the energy density.

Let us consider one-component fluids, where the order parameter is the number density $n$. In the van der Waals theory the energy density $e$ and the entropy $s$ per particle are given by $e = \frac{dnkT}{2} \ln T + \ln(\frac{1}{\nu_0 n - 1})$ and $s = \frac{(d)}{2} \ln T + \ln(\frac{1}{\nu_0 n - 1}) + \text{const}$, respectively, in terms of $T$ and $n$ [5]. Here $\nu_0$ and $\epsilon$ represent the molecular volume and the magnitude of the attractive potential, respectively, and $d$ is the space dimensionality. To describe situations in the presence of interfaces, we generalize this description by including gradient contributions to the total entropy and the total internal energy as

$$ S = \int dr \left[ n s - \frac{1}{2} C \nabla n^2 \right], $$

$$ E = \int dr \left[ n \left( \frac{1}{2} K \nabla n^2 \right) e \right]. $$

The gradient terms represent a decrease of the entropy and an increase of the energy due to inhomogeneity of $n$. Here the internal energy density is written as

$$ \dot{e} = e + K \nabla n^2 / 2, $$

including the gradient part. We assume that the coefficients $C$ and $K$ are simply constants and that $s$ in Eq. (1) depends on $n$ and $e$ as

$$ s = \frac{k_{B}}{2} \ln \left[ (e/n + \epsilon \nu_0 n)^{d/2}(1/\nu_0 n - 1) \right] + \text{const}. $$

This relation follows from the van der Waals theory. Our scheme starts with Eqs. (1), (2), and (4), where the temperature is not yet introduced. We then define the local temperature $T = T(n, e)$ by

$$ \frac{1}{T} = \frac{\delta S}{\delta e} = n \left( \frac{\delta s}{\delta e} \right)_n, $$

where $n$ is fixed in the derivatives. This definition of $T$ is analogous to that in a microcanonical ensemble. We also define the local chemical potential $\mu$ (per particle) including the gradient contributions by

$$ \mu = -T \left( \frac{\delta S}{\delta n} \right)_e \equiv - \mu + T \nabla \cdot \frac{M}{T} \nabla n, $$

where $\dot{e}$ in Eq. (3) is fixed, $\mu = -T(\delta(ns)/\delta n)_e$, and

$$ M = CT + K. $$

Maximization of $S$ under a fixed total particle number $\int dr$ and a fixed total energy $E$ leads to the equilibrium conditions $T = \text{const}$ and $\mu = \text{const}$. As first derived by van der Waals [5,6], the equilibrium interface density profile $n = n(x)$ is determined by $\mu(n, T) - M d^2n/dx^2 = \mu_{\text{ex}}$ with the surface tension $\gamma = M \int_{-\infty}^{\infty} dx (dn/dx)^2$, where $\mu_{\text{ex}}$ is the chemical potential on the coexistence curve [7].

Next we set up the dynamic equations [8]. Hereafter gravity is neglected. The mass density $\rho = mn$ (the particle mass) obeys $\partial \rho / \partial t = - \nabla \cdot (\rho \dot{v})$, where $\dot{v}$ is the velocity field. The momentum density $\rho \dot{v}$ obeys

$$ \frac{\partial}{\partial t} \rho v = - \nabla \cdot (\rho \dot{v}) - \nabla \cdot (\ddot{\Pi} - \sigma). $$

The $\ddot{\Pi} = \{\Pi_{ij}\}$ is the reversible stress tensor invariant with respect to time reversal $\dot{v} \rightarrow -\dot{v}$. The $\sigma = \{\sigma_{ij}\}$ is the dissipative stress tensor of the form $\sigma_{ij} = \eta(\nabla_i \nu_j + \nabla_j \nu_i) + (\zeta - 2\eta/d)\delta_{ij}\nabla \cdot v$ with $\nu_i = \partial / \partial x_i$ in terms of the viscosities $\eta$ and $\zeta$. The (total) energy density $e_t = \dot{e} + \rho \dot{v}^2 / 2$ including the kinetic part is governed by

$$ \frac{\partial}{\partial t} e_t = - \nabla \cdot \left[ e_t \dot{v} + \left( \ddot{\Pi} - \sigma \right) \cdot v \right] + \nabla \cdot (\lambda \nabla T), $$

where $\lambda = \frac{\partial \mu}{\partial T}$ and $\lambda_{\text{ex}} = \lambda_{\text{ex}}(T)$, which we will discuss in another paper [9].

where \( \lambda \) is the thermal conductivity. We construct the stress tensor \( \Pi_{ij} \) such that the entropy production rate within the fluid assumes the usual form [8],

\[
\frac{\partial}{\partial t} S = \int d\mathbf{r} \frac{1}{T} \left[ \nabla \cdot \left( \lambda \nabla T + \sum_{ij} \sigma_{ij} \nabla v_j \right) \right]. \tag{10}
\]

If there is no heat flow from outside, the above quantity becomes non-negative-definite. To obtain Eq. (10) we need to require the general relation,

\[
\nabla \cdot \left( \frac{1}{T} \Pi \right) = -n \nabla \left( \frac{\partial}{\partial n} S \right) \dot{\varepsilon} - \dot{\varepsilon} \nabla \left( \frac{\partial}{\partial \dot{\varepsilon}} S \right)_n. \tag{11}
\]

Using the van der Waals pressure \( p = nk_B T/(1 - \nu_0 n) - \epsilon \nu_0 n^2 \) we then find

\[
\Pi_{ij} = (p + p_1) \delta_{ij} - M \nabla n \nabla n, \tag{12}
\]

where \( p_1 = M(n \nabla n + |\nabla n|^2)/2 + T n \nabla n \cdot \nabla (M/T) \).

As an example, we consider a bubble with radius \( R \) in heat flow. Thermocapillary bubble migration has long been observed, especially in space [9–11]. Theoretically, however, the bubble motion has been examined in the absence of first-order phase transition at the interface such as in the case of air bubbles in silicone oil [9]. In such cases the temperature dependence of the surface tension \( \gamma \) causes a bubble velocity of order \( \nu_0 = R \gamma_1 (dT/dz)_0/\eta \) in a given temperature gradient \( (dT/dz)_0 \) (Marangoni effect), where \( \gamma_1 = -d \gamma/dT > 0 \) and \( \eta \) is the viscosity in liquid. In one-component fluids the effect is drastically altered due to latent heat generation or absorption at the interface [12]. We point out that a convective velocity of order \( \nu_0 = R \gamma_1 (dT/dz)_0/\rho' T \Delta s \) inside the bubble is sufficient to carry the applied heat flux, where \( \rho' \) is the mass density in gas, \( \Delta s \) is the entropy difference between gas and liquid per unit mass, and \( \lambda \) is the thermal conductivity in liquid. Note that the ratio

\[
M_i = \nu_0 / \nu_0 = R \gamma_1 \rho' T \Delta s / \eta \lambda \tag{13}
\]

is a very large number of order \( R/\alpha \) with \( \alpha \) being a microscopic length. With phase change the bubble velocity is of order \( \nu_0 \) and is very slow [12]. Furthermore, the temperature inside the bubble should be nearly homogeneous due to the latent heat convection. This is a natural consequence in one-component fluids without contamination [1,12], because the pressure should become nearly homogeneous outside the bubble and the fluid near the interface should be close to the coexistence curve in the \( p-T \) phase diagram.

In our simulation we set \( K = 0 \), and then the interface thickness is \( \ell = (C \nu_0 / 2 k_B)^{1/2} \) far from the critical point [since \( (\mu - \mu_{\text{cr}})/k_B T \) is of order 1 for \( n \sim \nu_0^{-1} \)]. Space is measured in units of \( \ell \), and the system length is \( L = 202 \ell \). Time is measured in units of \( t_0 = m \ell^2 / \eta \nu_0 \). We assume constant viscosities with \( \eta = \zeta \). The strength of dissipation is represented by the normalized viscosity \( \eta^* = \nu_0 \eta / \ell \zeta m \dot{\varepsilon} \). We set \( \eta^* = 0.1^{1/2} \). On all the boundary walls we assume [13,14]

\[
\Delta T / T_c = 0.00675
\]

FIG. 1. Suspended gas droplet in a steady state in heat flow with \( \Delta T = 0.00675T_c \). The arrows indicate the velocity.

\[
n = n_w + \ell_w \mathbf{v} \cdot \nabla n, \tag{14}
\]

where \( \mathbf{v} \) is the inward normal unit vector at the surface. We set \( n_w = 5n_c/2 \) and \( \ell_w = 2 \sqrt{2} \ell \), for which the wall is wetted by liquid in equilibrium in our simulation. We prepared an initial equilibrium state with a circular gas bubble with radius 50 placed at the center of the cell. The temperature was at \( T = 0.875T_c \), where the density is \( 0.37n_c \) in gas and 1.74\( n_c \) in liquid. The bottom boundary \( (y = 0) \) was then increased by a constant \( \Delta T \), while the top boundary \( (y = L) \) was held at the initial temperature \( T_1 = 0.875T_c \). (Here we use “bottom” and “top” though no gravity is assumed.) The side boundaries \( (x = 0 \) and \( L \) \) are insulating \( (\mathbf{v} \cdot \nabla n = 0) \). Furthermore, the density dependence of the thermal conductivity is crucial away from criticality [15], so we set \( \lambda = (\nu_0 \eta / k_B m) n \) with the ther-
Fig. 4. The velocity field around the gas droplet at \( t = 8 \times 10^4 \) in Fig. 3.

Fig. 5. The temperature in the nearly steady state in Fig. 4.

Fig. 6. Time evolution for \( \Delta T = 0.10125 T_c \). Phase separation occurs at the bottom. The bottom is completely wetted by gas in the steady state.
In summary, we have developed a scheme to study phase transition dynamics with inhomogeneous temperature under mass and heat fluxes. It can serve as a phase field model in fluids, though we should examine its sharp-interface limit [19]. For one-component fluids we mention wetting dynamics with evaporation and condensation [2,13], as exemplified here, and boiling or convection in gravity [4,5]. These effects can in principle be studied in the scheme of thermocapillary hydrodynamics supplemented with interface conditions. However, hydrodynamic calculations accounting for latent heat transport have rarely been performed.
