We study correlation functions of the energy-momentum tensor (EMT) in $(2+1)$-flavor full QCD
to evaluate QGP viscosities. We adopt nonperturbatively improved Wilson fermion and Iwasaki
gauge action. Our degenerate $u$, $d$ quark mass is rather heavy with $m_q/m_\rho \simeq 0.63$, while the $s$
quark mass is set to approximately its physical value. Performing simulations on lattices with
$N_t = 16$ to 6 at a fine lattice spacing of $a = 0.07$ fm, the temperature range of $T \simeq 174$–464 MeV
is covered using the fixed-scale approach. We attempt to compute viscosities by three steps: (1)
calculate two point correlation functions of non-perturbatively renormalized EMT applying the
gradient flow method, (2) derive the spectral function from correlation function, and (3) extract
viscosities from the spectral function applying the Kubo formula. We report on the status of the
project and present preliminary results for the shear viscosity in the high temperature phase.

1. Introduction

Ever since the heavy ion collision experiments went over the QCD phase transition temperature, the physical property of the quark gluon plasma (QGP) has been one of the most fascinating topics in high energy physics. The discovery of the large elliptic flow indicates that a kind of collective motion exists in QGP, and the success of the hydrodynamic models suggests that the QGP near the critical temperature is in a strongly coupled liquid state rather than a gas state (for a review see [1] and references therein). Furthermore, the comparison between hydrodynamic models and experimental data indicates that the shear viscosity of the QGP is quite small with $\frac{\eta}{s} \sim 0.2$, suggesting that the QGP liquid found is the most perfect fluid we have ever seen (for a review see Ref. [2]).

Inspired by the progress of experiment, there have been challenges in the lattice QCD community to calculate viscosities of QGP [3, 4, 5, 6, 7]. Viscosities can be extracted from the correlation function of the energy-momentum tensor (EMT) applying Kubo’s linear response relations. There are two major difficulties in this procedure to be carried out on the lattice. Firstly, the lack of translational symmetry on the lattice makes a definition of EMT not trivial. Secondly, the Kubo’s response function is defined in the real time formalism and thus not directly calculable in the Euclidean space time. We need to use the spectral function to relate the Matsubara Green’s function in the imaginary time formalism to the Kubo’s response function. However, a derivation of the continuous spectral function is an ill-posed problem on a finite lattice. Because of these difficulties, studies of viscosity on the lattice have been limited to the pure SU(3) theory without quarks.

We solve the first difficulty by adopting the gradient flow method [8, 9, 10] as a non-perturbative renormalization scheme for the EMT [11, 12]. In Ref. [13], we have computed the one-point function of EMT in $N_f = 2 + 1$ full QCD with the gradient flow method, and found that the results for the diagonal elements of EMT are well consistent with the equation of state evaluated previously with the conventional $T$-integration method. We now compute two-point functions of diagonal as well as off-diagonal elements of EMT. For the second difficulty, we try a couple of ansätze for the spectral function to fit the correlation functions in this study. By virtue of the gradient flow the correlation function is evaluated with a good precision and the fit works well.

2. Viscosities

The shear viscosity $\eta$ is given by a proportional coefficient in the stress tensor (spatial components of EMT) against a gradient of the velocity field $u_i$ for sufficiently long wavelength and slow mode

$$\langle T_{ij} \rangle_\beta = -\eta \partial_i u_j, \quad (i \neq j), \quad (2.1)$$

where

$$\langle T_{ii} \rangle_\beta = \frac{\text{Tr}(\exp(-\beta H) T_{ii})}{\text{Tr} \exp(-\beta H)} \quad (2.2)$$

with $\beta$ the inverse temperature and $H$ the Hamiltonian. The bulk viscosity $\zeta$ is given in a similar manner, $\langle T_{ii} \rangle_\beta = -\zeta \partial_i u_i$ where $i$ is not summed over.
In thermal equilibrium, however, the medium is isotropic and we have \( \langle T_{ij}\rangle_{\beta} = 0 \) for \( i \neq j \). This is consistent with a fact that hydrodynamics is a non-equilibrium phenomenon. We thus introduce the translational invariance in space-time we finally get linear response relations for the viscosities

\[
\langle T_{ij}(t,\vec{x})\rangle_u = \frac{1}{Z_u} \text{Tr} \left[ \exp \left( -\beta H + \beta \int d^3 x T^{0l}(\vec{x}) u_l(\vec{x}) \right) T_{ij}(t,\vec{x}) \right], \tag{2.3}
\]

\[
Z_u = \text{Tr} \exp \left( -\beta H + \beta \int d^3 x T^{0l}(\vec{x}) u_l(\vec{x}) \right), \tag{2.4}
\]

where \((t,\vec{x})\) is a coordinate of the Minkowski space-time with \( \eta_{\mu\nu} = (+---) \). Using a relation

\[
\exp \left( -\beta H + \beta \int d^3 x T^{0l}(\vec{x}) u_l(\vec{x}) \right) = \exp (-\beta H) T_{\tau} \exp \left( \int_0^\beta d\tau \int d^3 x T^{0l}(-i\tau,\vec{x}) u_l(\vec{x}) \right)
\]

with \( T^{0l}(-i\tau,\vec{x}) = e^{i\tau H} T^{0l}(\vec{x}) e^{-i\tau H} \) and \( T_{\tau} \) for the \( \tau \)-ordered product operation, we expand the expectation value to the leading order in \( u_l \),

\[
\langle T_{ij}(t,\vec{x})\rangle_u = \int_0^\beta d\tau \int d^3 x' \left\langle \Delta T_{ij}(t-i\tau,\vec{x}) \Delta T^{0l}(0,\vec{x}') \right\rangle_{\beta} u_l(\vec{x}'), \tag{2.5}
\]

where \( \Delta T_{ij} = T_{ij} - \langle T_{ij}\rangle_{\beta} \).

Making use of the conservation of EMT, the translation invariance and the time reversal symmetry in real time, we have

\[
\langle T_{ij}(t,\vec{x})\rangle_u = -\int_0^t ds \int d^3 x' \int_0^\beta d\tau \left\langle \Delta T_{ij}(s-i\tau,\vec{x}) \Delta T^{kl}(0,\vec{x}') \right\rangle_{\beta} \partial_s u_l(\vec{x}'). \tag{2.6}
\]

Assuming a uniform gradient for the velocity field \( u_l(\vec{x}) \) we extract the viscosity. Further applying the translational invariance in space-time we finally get linear response relations for the viscosities

\[
\eta = \int_0^\infty dt \int d^3 x \int_0^\beta d\tau \left\langle \Delta T_{ij}(t-i\tau,\vec{x}) \Delta T_{ij}(0,\vec{0}) \right\rangle_{\beta}, \tag{2.7}
\]

\[
\zeta = \int_0^\infty dt \int d^3 x \int_0^\beta d\tau \left\langle \Delta T_{ij}(t-i\tau,\vec{x}) \Delta T_{kl}(0,\vec{0}) \right\rangle_{\beta}, \tag{2.8}
\]

where sum is not taken over spatial indices.

The Kubo’s canonical correlation in the right hand sides of (2.7) and (2.8) is defined in the real time formalism and is not simply available on the lattice with Euclidean time. We use the spectral function to relate Kubo’s response function to the Matsubara Green function in Euclidean time. The spectral function is defined as usual

\[
\rho_{ijkl}(k) \equiv \int d^4 x e^{ikx} \left\langle [T_{ij}(x), T_{kl}(0)] \right\rangle_{\beta}. \tag{2.9}
\]

It is easy to show that both the Kubo and Matsubara Green functions are related with the spectral function as follows

\[
\int d^3 x \langle T_{ij}(-i\tau,\vec{x}) T_{kl}(0,\vec{0}) \rangle_{\beta} = \int_0^\infty \frac{dk_0}{2\pi} \frac{\cosh k_0 \left( \tau - \frac{\beta}{2} \right)}{\sinh k_0 \frac{\beta}{2}} \rho_{ijkl}(k_0,\vec{0}), \tag{2.10}
\]

\[
\int_0^\beta d\tau \int_{-\infty}^\infty dt e^{ik_0 t} \int d^3 x e^{-ik_0 x} \langle T_{ij}(t-i\tau,\vec{x}) T_{kl}(0,\vec{0}) \rangle_{\beta} = \frac{\rho_{ijkl}(k)}{k_0}. \tag{2.11}
\]
4. Numerical results

Measurements of EMT with the gradient flow method are performed on the \( N_f = 2 + 1 \) gauge configurations generated for Ref. [15]. The zero-temperature gauge configurations were generated...
Study of energy-momentum tensor correlation function

Yusuke Taniguchi

Figure 1: EMT correlation function $\sum_x \langle T_{ij}(t; \vec{x}, x_4) T_{ij}(t; 0) \rangle$ as function of Euclidean time $x_4$ at flow time $t/a^2 = 0.5$ (blue square), 1.0 (green circle), 1.5 (orange up triangle) and 2.0 (red down triangle). From the top left to the bottom the temperature is $T \simeq$ 174, 199, 232, 279, 348 and 464 MeV ($N_t = 16, 14, 12, 10, 8$ and 6, respectively). Solid lines are the fits with the Breit-Wigner fit ansatz using data between two dotted vertical lines.

Figure 2: The shear viscosity divided by the entropy density $\eta/s$ as a function of the flow time. $\eta/s$ is extracted by fitting the correlation function with the Breit-Wigner ansatz. We take the $t \to 0$ limit with a linear fit using the fit range indicated by two dotted vertical lines.

for Ref. [16]. The nonperturbatively $O(a)$-improved Wilson quark action and the renormalization-group improved Iwasaki gauge action are adopted. The bare coupling constant is set to $\beta = 2.05$, which corresponds to $a = 0.0701(29)$ fm ($1/a \simeq 2.79$ GeV). The hopping parameters are set to $\kappa_u = \kappa_d = \kappa_{ud} = 0.1356$ and $\kappa_s = 0.1351$, which correspond to heavy $u$ and $d$ quarks, $m_\pi/m_\rho \simeq 0.63$, and almost physical $s$ quark, $m_\eta_c/m_\rho \simeq 0.74$. We adopt the fixed-scale approach [17] in which the temperature $T = 1/(aN_t)$ is varied by changing the temporal lattice size $N_t$ with a fixed lattice spacing $a$. The temperature varies $174 \leq T \leq 464$ MeV with temporal length $16 \geq N_t \geq 6$. See Ref. [13] for a detailed explanation of numerical parameters.

In Fig. 1 we plot the shear correlation function $\sum_x \langle T_{ij}(t; \vec{x}, x_4) T_{ij}(t; 0) \rangle$ as function of Euclidean time $x_4$ at four different flow times $t$ for six different temperatures $T$ shown in each panel.
Figure 3: Preliminary results for the shear viscosity divided by the entropy density, $\eta/s$, as a function of the temperature. The viscosity is extracted by fitting the correlation function with the Breit-Wigner ansatz (black circles) and the hard thermal loop ansatz (red triangles). The blue solid line is $1/4\pi$ from the AdS/CFT correspondence. The right panel is the same but differs in vertical scale.

Indices are averaged over all $i \neq j$ combinations. Within the fit range indicated by the vertical dotted lines, the Breit-Wigner ansatz (3.4) fits the data well with $\chi^2/\text{dof} < 2$ at low temperatures $T \leq 279$ MeV. On the other hand, $\chi^2/\text{dof}$ exceeds ten at higher temperatures.

The results for the shear viscosity divided by the entropy density, $\eta/s$, is plotted in Fig. 2 as a function of the flow time at six temperatures. We take the $t \to 0$ limit by using data within the region shown by two vertical dotted lines. Our preliminary results for $\eta/s$ by the Breit-Wigner ansatz at each temperature are summarized in the first row of Table 1 and are plotted in Fig. 3 by black circles.

The same procedure works well also with the hard thermal loop fit ansatz (3.5). Our preliminary results for $\eta/s$ by the hard thermal loop ansatz are summarized in the second row of Table 1 and are plotted in Fig. 3 by red triangles.

For the bulk viscosity $\zeta$, we find that our diagonal correlation function $\sum_i \langle T_{ii}(t; x, x_4) T_{ii}(t; 0) \rangle$ is statistically not fine enough to extract a non-trivial value of $\zeta/s$. Both with Breit-Wigner and hard thermal loop fit ansätze, we find large $\chi^2/\text{dof}$ above five. The resultant values of $\zeta/s$ are consistent with zero with large statistical error for all temperatures we studied.

5. Conclusion

We calculated two point correlation functions of the energy-momentum tensor (EMT) in lattice QCD with $(2 + 1)$-flavors at finite temperature, $174 \leq T \leq 464$ MeV. Nonperturbatively renormalized EMT is calculated by applying the gradient flow renormalization scheme. By virtue of the gradient flow, statistical error is suppressed at finite flow time and the correlation functions are evaluated with a good precision. We apply two types of model fit for the correlation function to extract the spectral function. The procedure works well for the shear correlation func-

| T[MeV] | 174    | 199    | 232    | 279    | 348    | 464    |
|--------|--------|--------|--------|--------|--------|--------|
| BW ansatz | 2.3(2.7) | 0.00(23) | 0.145(51) | 0.240(47) | 0.1753(53) | 0.175(11) |
| HTL ansatz | 2.52(47) | 0.59(16) | 0.208(38) | 0.24(10) | 0.05(12) | 0.061(11) |
tion $\sum_{\vec{x}} \langle T_{ij}(t;\vec{x},x_4) T_{ij}(t;0) \rangle$. Our preliminary results for the shear viscosity are given in Fig. 3 and Table 1 as a function of temperature. The resultant shear viscosity seems to be consistent with the small experimental value given in Ref. 2 well above the pseudo-critical temperature $T_{pc} \approx 190$ MeV. On the other hand, we need a higher statistics for the bulk viscosity.
