Fabricating hierarchical core-shell nanostructures is currently the subject of intensive research in the electrochemical field owing to the hopes it raises for making efficient electrodes for high-performance supercapacitors. Here, we develop a simple and cost-effective approach to prepare CuO@MnO₂ core-shell nanostructures without any surfactants and report their applications as electrodes for supercapacitors. An asymmetric supercapacitor with CuO@MnO₂ core-shell nanostructure as the positive electrode and activated microwave exfoliated graphite oxide (MEGO) as the negative electrode yields an energy density of 22.1 Wh kg⁻¹ and a maximum power density of 85.6 kW kg⁻¹; the device shows a long-term cycling stability which retains 101.5% of its initial capacitance even after 10000 cycles. Such a facile strategy to fabricate the hierarchical CuO@MnO₂ core-shell nanostructure with significantly improved functionalities opens up a novel avenue to design electrode materials on demand for high-performance supercapacitor applications.

Supercapacitors, known as electrochemical capacitors, hold substantial promise for next-generation power devices due to their excellent properties such as high power density, fast charge and discharge rate, excellent reversibility, and long cycle life²⁻⁴. In general, they can be divided into two categories in light of their charge storage mechanisms: the electric double-layer capacitors (EDLCs) and the pseudo-capacitors⁵⁻⁹. To date, much effort has been devoted to the latter using transition-metal oxides including MnO₂¹⁰,¹¹, Co₃O₄¹²,¹³, NiO¹⁴,¹⁵, VOₓ¹⁶,¹⁷, and CuO¹⁸⁻²⁰ because they bear a much higher specific capacitance and energy density compared to carbon-based materials and conducting polymers. Moreover, they have a variety of oxidation states so as to allow the efficient redox charge transfer. Among the available transition-metal oxides, MnO₂ has attracted a great deal of attention for its role as an electrode material for supercapacitors due to its abundance, high theoretical capacity (~1370 F g⁻¹), non-toxicity, and wide operating potential range in mild electrolyte²¹⁻²⁵. It is thus currently the subject of intensive research to fabricate MnO₂ with different morphologies and examine associated electrochemical properties. However, the key issues limiting its widespread applications rest with its low surface area and poor electronic conductivity. To overcome the issues, many techniques have been attempted, yet most of them involve the preparation of MnO₂-conductive matrix hybrid nanostructures through incorporating MnO₂ with conductive support²⁶⁻³². Such hybrid system can show high-rate and cycling ability due to the relatively low weight fraction of its active materials. However, it has low energy density. Although this can be resolved by developing novel hybrid pseudo-capacitive systems via combining the metal oxides with binary metal oxide/hydroxides, the electrochemical performance of these systems remains unsatisfactory. This is due to the intricacies in fabricating well defined micro/nano-structure and also because of lack of knowledge of the synergistic effects³³,³⁴. To address these issues, the MnO₂-based nanocomposites with a range of morphologies has been developed as electrodes for supercapacitors, aimed to enhance their electrochemical function, including Co₃O₄@MnO₂, Fe₃O₄@MnO₂, ZnO@MnO₂, TiO₂@MnO₂, NiCo₂O₄@MnO₂, and Co₃O₄@Pt@MnO₂³³,³⁵⁻⁴⁰. Taking the amount of challenges and opportunities, creating integrated smart architectures with well-defined structures, improved electroactivity, and faster ion and electron transport is timely and important.
Here, we developed a simple and cost-effective method to fabricate hierarchical CuO@MnO₂ core-shell heterostructures as electrode materials for high-performance supercapacitors. We systematically probed structures and electrochemical properties of the heterostructures in which the CuO nanowires/nanotubes are designed as core, while the ultrathin MnO₂ nanosheets as shell. The complex heterostructures are found to show a high specific capacitance of 276 F g⁻¹ at a current density of 0.6 A g⁻¹, much improved rate performance, and long-term cycling stability (92.1% of its original value after 1000 cycles), rendering such heterostructures promising for the application as high-performance supercapacitors.

Results

To determine the chemical composition and crystallite phase of the CuO@MnO₂ nanocomposites, we performed X-ray diffraction (XRD) analyses, as shown in Fig. 1, where XRD pattern of freshly prepared Cu nanowires is given as well (Supplementary Fig. S1). When the reaction time is 1 h, three sharp peaks occur at 2θ = 43.5, 50.7, and 74.48°, which are correspondingly indexed as (111), (200) and (220) planes of face-centered cubic Cu (JCPDS card no. 03-1018). The diffraction peaks at 2θ = 12.5°, 25.2°, 37° and 65.6° are, on the other hand, in line with standard XRD patterns of the birnessite-type manganese oxide crystal (JCPDS card no. 80-1098), which reveals the formation of MnO₂. When the reaction time is over 12 h, sharp peaks of Cu nanowires disappear. The weak peaks of CuO are detected instead, indicating that Cu nanowires are almost transformed to CuO. The samples prepared after over 24 h are found to be composed of mixed CuO and ⁵⁻MnO₂. We also find that the crystallinity is somewhat enhanced with the increase of hydrothermal reaction time.

Figure 2 presents SEM images of the samples prepared at different hydrothermal time. From Fig. 2a and b, one can see that surfaces of pristine Cu nanowires are rough and uniformly covered by close-packed MnO₂ nanoparticles. By contrast, the freshly prepared pristine Cu nanowires have a smoother surface (Supplementary Fig. S2). As the reaction time is over 12 h, surfaces of Cu nanowire are homogeneously covered by ultrathin MnO₂ nanoflakes (Fig. 2c). On closer inspection, the individual hierarchical CuO@MnO₂ nanotube is determined to have a diameter of ~400 nm (Fig. 2d), much larger than the pristine Cu nanowires (90–150 nm). When the reaction time reaches 24 h, the CuO surfaces are covered by compact MnO₂ nanosheets (Fig. 2e and f), and the composites have a diameter of 700 nm, indicative of sufficient reaction of KMnO₄. However, when the reaction time is 48 h, there appear MnO₂ nanoflowers comprising nanosheets, which is due to the Ostwald ripening process⁴¹,⁴², leading to self-assembly of small nanosheets to hierarchical nanostructures.

Figure 3 shows a typical TEM image of the hybrid CuO@MnO₂ nanocomposite prepared using 0.05 M KMnO₄ at 160°C for 24 h. The surfaces of CuO nanotubes are uniformly covered by thin nanosheets (Fig. 3a and b), as confirmed in the scanning TEM (STEM) image (Supplementary Fig. S3b). Further analysis of the SAED pattern (Fig. 3b, inset) taken from the nanosheet edge reveals that the birnessite-type MnO₂ is polycrystalline⁴³,⁴⁴. From the HRTEM image (Fig. 3c), one can clearly see the lattice fringes with an interplanar spacing of 0.69 nm for the two curling nanosheets, which is identified as the typical interplanar spacing of the (001) plane of birnessite-type MnO₂. Energy-dispersive x-ray spectroscopy (EDS) analysis of individual composite reveals that there appears a distribution of O, K, Mn, and Cu across the core-shell structure (Fig. 3d and Supplementary Fig. S3). Interestingly, the K, Mn and O signals are detected in the entire structure, verifying that the core-shell is composed of hollow CuO nanotube supported MnO₂ nanosheets (Fig. 3d). This unique structure helps improve ionic transport and mechanical stability. We also prepared hybrid nanocomposites with 0.05 M KMnO₄ for 12 h, and identified that the CuO core is not completely hollow (Supplementary Fig. S4), indicating that reaction time is crucial to structural evolution of CuO interiors.

We therefore propose a possible growth mechanism for the hybrid CuO@MnO₂ core-shell structure (Fig. 4), which can be divided into three stages. Firstly, the MnO₂ nuclei are produced and adsorbed on surfaces of Cu nanowires, forming MnO₂ nuclei. With the increase of reaction time, the MnO₂ nuclei are aggregated and transformed to nanosheets. In the meanwhile, Cu nanowires are oxidized to CuO nanowires, followed by a transformation to CuO nanotubes. Finally, the MnO₂ nanosheets are compact and totally cover surfaces of CuO nanotubes, resulting in the formation of the hierarchical CuO nanotube@MnO₂ nanosheets nanocomposites. Such process is supported by the morphology evolution at different growth stages via tuning the reaction time (Fig. 4).

The formation of CuO nanotubes can also be explained by the mechanism similar to the Kirkendall effect at metal/oxide interface: the outward diffusion of metal ions is much faster than inward oxygen diffusion induced by the decomposition of KMnO₄ in hydrothermal reaction. The vacancies, which can diffuse to metals as a counterflow to the outward diffusion of metallic ions, can aggregate to generate voids. Such growth mechanism for the CuO nanotubes is in line with previous studies demonstrating that formation of oxide nanotube is through the Kirkendall-type diffusion process⁴⁵−⁴⁷. It is worthy of noting that the interconnected MnO₂ nanosheets and hollow CuO nanotubes give rise to a highly porous morphology, which can offer very high surface area and a large number of active sites for the adsorption of Na⁺. These eventually lead to a high specific capacitance for CuO@MnO₂ composite. We therefore attribute the observed growth mechanism to a synergistic effect of Ostwald ripening process⁴⁸ which forms MnO₂ nanosheets and Kirkendall-type diffusion process⁴⁹ which is responsible for the formation of CuO nanotubes. Furthermore, we investigated the effect of concentration of KMnO₄ and reaction temperature on morphology of the composite and find that the relatively high concentration of KMnO₄ and high temperature favor the formation of the hierarchical CuO nanotube@MnO₂ nanosheets architectures (Supplementary Figs. S5 and S6).

Figure 5 shows XPS spectra of the composite, which are calibrated with reference to C 1s peak at 285 eV. The Mn 2p XPS spectrum exhibits two major peaks at binding energy of 654.75 and 642.95 eV with a spin–energy separation of 11.8 eV (Fig. 5a), in agreement with other reports⁵⁰−⁵². As reported previously⁵³−⁵⁵, the average oxidation state of Mn in manganese oxides can be determined by the energy separation of Mn 3s peaks. The CuO@MnO₂ hybrid structures exhibit a separated energy of 4.8 eV for the Mn 3s doublet (Fig. 5b), indicating that the Mn in the composite has a charge state of ~4.0. Figure 5c shows XPS of Cu 2p core level, from which the peaks at 954.2 and 934.45 eV are found to correspond to the Cu 2p₁/₂ and Cu 2p₃/₂, respectively, with a spin-orbit splitting of 19.75 eV. There are also two satellite peaks at 962.7 and 943.65 eV, which
confirms the oxide in the sample as CuO\textsuperscript{18,53,54}. These results also confirm the formation of CuO@MnO\textsubscript{2} composite, in good agreement with the XRD analysis. In addition, the fitted O 1\textsuperscript{s}s spectrum is characterized by three bands (Fig. 5d): two at 532.3 and 531.3 eV, which is due to the absorption of oxygen and water molecules on the composite surface, and one at 530.4 eV, which corresponds to the O\textsuperscript{2} band with Cu and Mn\textsuperscript{39,55}. We also investigated XPS spectra of CuO/MnO\textsubscript{2} composite fabricated after 1 h, revealing the presence of the fitted Cu 2\textsuperscript{p} spectrum. This also implies that Cu nanowires are, to some extent, oxidized even after reaction for 1 h (Supplementary Fig. S7).

To investigate surface property of the composite, we conducted FT-IR spectrum analysis. As shown in Fig. 6a, the broad band at \(~3440\text{ cm}^{-1}\) indicates O–H stretching in water molecules, and the weak band at 1635 cm\textsuperscript{-1} may be due to bending vibration of O–H groups in the adsorbed water molecules. The peaks at \(~1385\text{ and }1117\text{ cm}^{-1}\) correspond to the coordination of Mn by the O–H. The peak at 529 cm\textsuperscript{-1} is deemed as the main characteristic absorption band of birnessite, which corresponds to the Mn–O stretching modes of the octahedral layers in the birnessite\textsuperscript{11}. Moreover, the weak band at 448 cm\textsuperscript{-1} can be due to the Cu–O stretching vibration. We therefore conclude that the products are mixed CuO and MnO\textsubscript{2}, in good agreement with the XRD analysis.

Figure 6b shows thermal stability of the as-synthesized composite, where one can see the first weight loss (\(~11.5\%\)) below 180°C, which is attributed to the removal of physically absorbed water and chemically bonded water. There are two endothermic DSC peaks at \(80^\circ\text{C}\) and \(150^\circ\text{C}\), confirming the water evaporation. This feature can also be reflected in the TGA analysis. The second weight loss (\(~2\%\)) in between 550 and 700°C can be attributed to the loss of oxygen in MnO\textsubscript{2} lattice, \textit{i.e.} reduction of MnO\textsubscript{2} to Mn\textsubscript{2}O\textsubscript{3}\textsuperscript{42,56,57}, consistent with the sharp peak in the DSC curve.

To further investigate the surface property of the as-prepared nanocomposite, we measured the Brunauer-Emmett-Teller (BET)
and nitrogen adsorption-desorption, as shown in Fig. 7. The nanocomposite shows a typical type IV isotherm with hysteresis loop in a relative pressure (P/P₀) range of 0.7–1.0, implying the formation of slit-like pores by stacking the sheet-like MnO₂ building blocks. The BET surface area of the core-shell nanostructure is calculated to be 98 m² g⁻¹, and mean diameter of the pores is calculated to be 5 nm using Barrett-Joyner-Halenda (BJH) model. The high BET specific surface area and mesoporous structure can enhance electron and ion transport, resulting in high electrochemical capacity for the nanocomposite. We also prepared nanocomposites with different reaction time and examined N₂ adsorption/desorption isotherms (Supplementary Fig. S8). We find that the nanocomposites obtained at 24 h show the largest BET surface area, which should broaden the contact area between the active materials and the electrolytes.

To evaluate the applications of the nanostructures as electrochemical capacitors, we fabricated electrodes in a three-electrode configuration (Fig. 8). Figure 8a presents the CV curves of CuO@MnO₂ electrodes in 1 M Na₂SO₄ aqueous electrolyte at various scan rates. Although there are no distinct redox peaks, the shape of CV curve deviates from the ideal rectangle, implying that the electrode shows faradic pseudocapacitive nature. To further investigate electrochemical performances of the CuO@MnO₂ electrode, we perform galvanostatic charge-discharge curves at various current densities in an electrochemical window of −0.2 ~ 0.8 V (Fig. 8b). There appear a triangular symmetry and linear slopes, consolidating the good electrochemical performance. The specific capacitance is calculated to be 276 F g⁻¹ from the discharge curves at a current density of 0.6 A g⁻¹, which can be attributed to the highly porous structure and high specific surface area which facilitate ion transfer and thus enhance redox faradic reactions and surface adsorption of electrolyte cations. It is worthy of noting that the nanocomposite shows a higher specific capacitance compared to the MnO₂-based electrodes reported previously (Supplementary Table S1).

We further investigated the relationship between the specific capacitance and the current density (Supplementary Fig. S9) and found that the capacitance decreases with the increase of current density.

Although there are no distinct redox peaks, the shape of CV curve deviates from the ideal rectangle, implying that the electrode shows faradic pseudocapacitive nature. To further investigate electrochemical performances of the CuO@MnO₂ electrode, we perform galvanostatic charge-discharge curves at various current densities in an electrochemical window of −0.2 ~ 0.8 V (Fig. 8b). There appear a triangular symmetry and linear slopes, consolidating the good electrochemical performance. The specific capacitance is calculated to be 276 F g⁻¹ from the discharge curves at a current density of 0.6 A g⁻¹, which can be attributed to the highly porous structure and high specific surface area which facilitate ion transfer and thus enhance redox faradic reactions and surface adsorption of electrolyte cations. It is worthy of noting that the nanocomposite shows a higher specific capacitance compared to the MnO₂-based electrodes reported previously (Supplementary Table S1).

We further investigated the relationship between the specific capacitance and the current density (Supplementary Fig. S9) and found that the capacitance decreases with the increase of current density.
The CuO@MnO₂ electrode displays a moderate rate, i.e. 51% of its initial capacitance, when the current density increases from 0.6 to 10 A g⁻¹. The low capacitance at high current density can be attributed to the decrease in the utilization efficiency of the active material. We also measured the electrochemical properties of the nanostructures prepared at different reaction time (Supplementary Fig. S10). The nanocomposite prepared at 24 h shows the highest specific capacitance, nearly 1.5 times higher than the one prepared at 1 h, which indicates that morphology plays an important role in affecting electrochemical property.

The impedances of MnO₂-modified diatomite hierarchical electrode before and after 1000 cycles are also measured in the frequency range of 100 kHz–0.01 Hz at an open circuit potential by employing an AC voltage of 5 mV. As shown in Fig. 8c, the impedance spectra are composed of one semicircle at high frequency, followed by a linear shape at low frequency. The inset of Fig. 6c gives an equivalent circuit used to fit the impedance curve, consistent with the one employed for the working electrode of the supercapacitor. The electrochemical impedance spectral data are fitted by the internal resistance (Rs), the charge-transfer resistance (Rct), the Warburg impedance (Zw), the constant phase element (CPE) to address the double-layer capacitance, and the CL to address the limited pseudofaradic reaction⁵⁸. Supplementary Table S2 lists the corresponding equivalent circuit parameters fitted in the Nyquist plots for the CuO@MnO₂ electrodes before and after 1000 charge/discharge cycles. The internal resistances (Rs) of the MnO₂ electrodes change from 1.0 Ω to 1.4 Ω after 1000 cycles, manifesting a good conductivity of the electrolyte and the very low internal resistance of the electrode. The charge-transfer resistance (Rct), however, increases only a little from 15.6 to 17.2 Ω after 1000 cycles. Further investigation demonstrates that the hierarchical CuO@MnO₂ nanostructured electrode exhibits excellent electrochemical cycling stability.

Figure 8d shows the cycling stability of the as-prepared hierarchical CuO@MnO₂ nanostructures by conducting charge/discharge tests at a current density of 3 A g⁻¹ for 1000 cycles. The specific capacitance of the CuO@MnO₂ electrode maintains 92.1% of its initial value, indicating a good stability. The charge-discharge curves of the final 10 cycles are shown in inset of Fig. 8d, showing almost the same symmetric shape, which implies that the CuO@MnO₂ electrode does not undergo significant structural change during the charge/discharge processes. Further SEM imaging of the electrode uncovers that the hierarchically porous CuO@MnO₂ core-shell structure is maintained (Supplementary Fig. S11). Such unique nanostructure may solve the aggregation and volume expansion issue during long-term cycles, which benefit the structural stability of the CuO@MnO₂ electrode. This also demonstrates that this...
nanocomposite can act as potential candidates for electrodes in supercapacitors.

**Discussion**

To test if the hybrid CuO@MnO2 electrodes can be put into real applications, we fabricated asymmetric supercapacitors using the CuO@MnO2 core-shell structures as positive electrode and the microwave exfoliated graphite oxide (MEGO) as negative electrode. The 1.0 M Na2SO4 aqueous electrolyte is applied. Figure 9a shows CV as a function of voltage for the CuO@MnO2//MEGO asymmetric supercapacitor with an optimal mass ratio between two electrodes. The CuO@MnO2 core-shell and MEGO materials have a weight of 0.8 and 1.0 mg, respectively. The supercapacitor shows an ideal capacitive behavior with quasi-rectangular CV curves at a scan rate of 50 mV s\(^{-1}\) even at the potential up to 2.0 V. The CV curves obtained under various scan rates at a voltage ranging from 0 to 1.8 V exhibit a rectangular-like shape (Fig. 9b), indicating that the device shows a fast charge/discharge behavior and a high rate ability.

Figure 9c shows galvanostatic charge/discharge curves, from which one can note that the potentials are nearly proportional to time, indicating a rapid I–V response and an ideal capacitive nature. The gravimetric capacitance (Ct) is calculated to be 49.2 F g\(^{-1}\) at current density of 0.25 A g\(^{-1}\). We further assess a maximum gravimetric energy density of 22.1 Wh kg\(^{-1}\) and power density of 85.6 kW kg\(^{-1}\) (Fig. 9d) for our asymmetric supercapacitor, much higher than those of symmetrical supercapacitor or MnO2-based asymmetric supercapacitor\(^{42,59–63}\). We further connected our prototype device to a red LED and successfully light the LED (inset in Fig. 9d). The LED is on for over 10 min after charged for 30 s at 1.8 V (Supplementary Movie S1). In addition, we tested the long-term cycle stability of this device at a current density of 3 Ag\(^{-1}\) for 10000 cycles, and found that the specific capacitance is increased gradually in the initial cycling test and turn steady. Although slight degradation tendency is observed in the final cycling test (Supplementary Fig. S12), the capacitance retains 101.5% of its initial value even after 10000 cycles, demonstrating a minimal damage and
behaviors adds instantly a novel practical route for the elegant design of MnO2 coaxial nanostructure with remarkably enhanced capacitive performance supercapacitors. By taking advantage of the hybridization of CuO and MnO2, we demonstrate that the electrode fabricated by the as-prepared CuO@MnO2 nanocomposite shows a specific capacitance of 276 F g−1. We also fabricate asymmetric supercapacitors in the form of fully packaged cells, and demonstrate that the device can be reversibly charged and discharged at an operation voltage of 1.8 V in 1.0 M Na2SO4 aqueous electrolyte. Moreover, the device delivers an energy density of 22.1 Wh kg−1, a maximum power density of 85.6 kW kg−1, and a long-term cycling stability which retains 101.5% of its initial capacitance even after 10000 cycles. The new CuO@MnO2 coaxial nanostructure with remarkably enhanced capacitive behaviors adds instantly a novel practical route for the elegant design of electrodes for high-performance supercapacitors.

Methods

Synthesis of Cu nanowires. All chemical regents were of analytical purity and used with no further purification, including the copper nitrate (Cu(NO3)2·3H2O), sodium hydrate (NaOH), ethylenediamine (EDA), hydroxide monohydrate (N2H·H2O, 98%), potassium permanganate (KMnO4), and ethanol (C2H5OH). The copper nanowires were prepared by reducing copper (II) nitrate with hydrazine in the alkaline medium46,64. An aqueous solution of Cu(NO3)2·3H2O (1 mL, 0.1 M) was mixed with NaOH (20 mL, 15 M). The ethylenediamine (EDA, 150 µL) and hydrazine (35 µL, 35 wt.%) were then added sequentially. The mixture was next stirred utterly. The reactor was placed in water bath at 65 °C for 1 h. Finally, the resulting products were filtered, washed with distilled water and ethanol several times, and dried at 60 °C in vacuum oven for 6 h.

Fabrication of the CuO nanotube@MnO2 nanosheet core-shell nanostructures. The CuO@MnO2 nanocomposites were prepared without any surfactant using a facile and scaleable method. First, the Cu nanowires (10 mg) were dispersed in KMnO4 solution (30 mL, 0.01–0.1 M) to form a homogeneous precursor. The mixture was then put into a Teflon-lined stainless steel autoclave which was subsequently maintained at 160 °C for 24 h. Finally, the sample was removed, washed with distilled water and ethanol, and dried at 60 °C.

Material characterization. The crystallography and chemical composition of the as-prepared products were investigated by powder X-ray diffraction (XRD, D/max 1200, Cu Kα) and Fourier transform infrared spectroscopy (FTIR, Nicolet 5DX). The morphologies of the CuO@MnO2 composites were observed with focused ion beam (Zeiss Auriga FIB/SEM). Microstructures were characterized by transmission electron microscopy (TEM), high-resolution TEM, and energy-dispersive x-ray spectroscopy (EDS) using JEOL, JEM-2100F electron microscope operated at 200 kV. The nitrogen adsorption-desorption isotherms were measured at 77 K using micrometrics ASAP 2020 sorptometer. Specific surface area was determined with Brunauer–Emmett–Teller (BET) equation, and the distribution of pore size was calculated from the adsorption curve by the Barrett–Joyner–Halenda (BJH) method.

Electrochemical measurements. A three-electrode system was applied to measure the response of CuO@MnO2 nanostuctures as working electrode. The Na2SO4 aqueous solution (1 M), platinum plate, and saturated calomel electrode (SCE) were employed as electrolyte, counter and reference electrode, respectively. The working electrode was prepared by mixing 70 wt% active material (CuO@MnO2), 20 wt% acetylene black and 10 wt% polyvinylidene fluoride (PVDF) in N-methyl-2-pyrrolidone (NMP). The slurry was spread onto a foam nickel current collector (1 × 1 cm²). The electrode was heated at 120 °C for 12 h to evaporate solvent and then uniaxially pressed under 10 MPa. The electrode contained 2–3 mg active CuO@MnO2 material.

The supercapacitor performance was measured using a two-electrode system that is composed of two slices of electrode materials with identical shape, a filter paper as separator, and two nickel foils as current collectors. In the two-electrode system, the CuO@MnO2 nanostuctures acted as a positive electrode. The negative electrode was prepared by putting the mixed paste of activated microwave exfoliated graphite oxide (MEGO) with 20 wt% acetylene black and 10 wt% polyvinylidene fluoride (PVDF) in N-methyl-2-pyrrolidone (NMP) onto the uniform sheets. The two electrodes were assembled together by soaking the filter paper in Na2SO4 solution in prior to be connected to potentiostat. The performances for both three-electrode and two-electrode configurations were measured with CHI 660E electrochemical station. The cyclic voltammetry (CV) and galvanostatic charge-discharge technique were used to probe electrochemical performance of the electrodes. The operating current density was calculated based on the mass of active materials, that is, the mass of CuO@MnO2 for the three-electrode system and the total weight of CuO@MnO2 and MEGO for the two-electrode system. Electrochemical impedance spectroscopy (EIS) was measured in the frequency range from 100 kHz to 0.01 Hz with perturbation amplitude of 5 mV.

Acknowledgments
This work was supported in part by the National Natural Science Foundation of China (Grant no. 51104194), the Doctoral Fund of Ministry of Education of China (2011019120019), the No. 43 Scientific Research Foundation for Returned Overseas Chinese Scholars, the National Key Laboratory of Fundamental Science of Micro/Nano-device and System Technology (2013MS06, Chongqing University), and the State Education Ministry and Fundamental Research Funds for Central Universities (Project no. CDJZR1224801, CDJZR12135501, and CDJZR13130035, Chongqing Univ., China). Z.C.W. thanks financial supports from the Grant-in-Aid for Young Scientists (A) (grant no. 24686069), the JGC-S Foundation, and the Kurata Memorial Hitachi Science and Technology Foundation.

Author contributions
Y.X.Z., Z.C.W. and Q.L. conceived and designed the experiments. M.H. prepared materials and electrodes, and wrote the manuscript. F.L. conducted electrochemical measurements. Z.Y.W., A.M. and N.H. assisted the observations and measurements. Y.X.Z., Z.C.W. and Q.L. discussed the results and directed the entire study. All authors read and commented on the paper.
