Despite their scarcity due to synthetic challenges, supertetrahedron-based metal–organic frameworks (MOFs) possess intriguing architectures, diverse functionalities, and superb properties that make them in-demand materials. Employing a new window-space-directed assembly strategy, a family of mesoporous zeolitic MOFs have been constructed herein from corner-shared supertetrahedra based on homometallic or heterometallic trimers \([M_3(OH/O)(COO)_6]\) \((M_3 = C_{o_2}, N_{i_3} or C_{o_2}Ti)\). These MOFs consisted of close-packed truncated octahedral cages possessing a sodalite topology and large \(\beta\)-cavity mesoporous cages (\(\sim 22 \text{ Å} \) diameter) connected by ultramicroporous apertures (\(\sim 5.6 \text{ Å} \) diameter). Notably, the supertetrahedron-based sodalite topology MOF combined with the \(C_{o_2}Ti\) trimer exhibited high thermal and chemical stability as well as the ability to efficiently separate acetylene (\(C_{2H_2}\)) from carbon dioxide (\(CO_2\)).

Introduction

Metal–organic frameworks (MOFs), which are typically obtained via the self-assembly of metal ions/clusters and organic ligands through coordination bonds, have been a topic of research due to their great potential for various applications, including gas storage and separation, heterogeneous catalysis, enzyme immobilization and others. The properties of MOFs are highly dependent on the inherent network topologies, which, in turn, are strongly influenced by the coordination geometry of the metal nodes and the shape of the component organic ligands. These fascinating MOF network topologies are designed and constructed using numerous rational approaches, of which the strategy employing supramolecular building blocks (SBBs) is a most popular one; here, metal–organic polyhedra are used as building blocks to assemble MOFs with large cavities and high-connectivity network topologies. Since supertetrahedron (ST), which is an enlarged \(SiO_4\) and \(AlO_4\) tetrahedral building unit of traditional inorganic zeolites, is a widely utilized SBB in MOF synthesis. Two of the most extensively studied mesoporous MOFs (MIL-100 and MIL-101) possess the same \(mtn\) zeolite topology, which results from corner-sharing STs whose vertices are occupied by chromium trimers. The presence of metal trimers in MOFs are known to accommodate single or multiple metal ions that exhibit excellent catalytic performance and exceptional gas adsorption and separation abilities. Of the numerous zeolitic network topologies reported, only two types can be categorized as zeolitic MOFs due to augmentation by STs based on metal trimers, namely, the \(mtn\) and \(\beta\)-crystobalite networks. This could be presumably due to the lack of large, high-quality crystals for single-crystal X-ray
diffraction (SCXRD) analysis and the complexity of the results obtained via powder X-ray diffraction (PXRD). Despite the associated challenges, the deliberate introduction of corner-shared STs based on metal trimers into MOFs with other zeolitic network topologies, especially those containing suitably sized single-crystals for SCXRD, is a crucial step toward understanding these materials.

The most thoroughly studied zeolitic imidazole framework to date is ZIF-8, which possesses a sodalite (sod) topology with a Brunauer–Emmett–Teller (BET) surface area of 1630 m² g⁻¹. ZIF-8 contains large β-cavities of approximately 11.6 Å in diameter that are accessible through narrow hexagonal windows. The square window of the β-cavity has a negligible diameter, whereas the hexagonal window is 3.4 Å in diameter. Significantly, ZIF-8 has a high uptake capacity as a result of its higher surface area and pore volume when compared with traditional inorganic zeolites. Furthermore, the presence of the ultramicroporous aperture in ZIF-8 facilitates its application for hydrocarbon separation via a molecular sieving effect. On the other hand, MOFs with the ultra-micropore scale (i.e., <7 Å) pore sizes are endowed with strong van der Waals interactions with adsorbed gas molecules. Therefore, the combination of ultramicroporous aperture, high surface area and pore volume could lead to the high gas storage and separation ability of MOFs. The adsorption capacity can be enhanced by extending the pore diameters of the β-cavities from the micro- to the mesoscale. However, this process is often complicated by enlarging the windows of the sod cage to afford pore apertures that are beyond the ultra-micropore scale, thereby weakening the interactions with gas molecules. We speculate that this issue can be addressed by partially closing the windows of the sod cage to retain ultramicroporous aperture thus strengthening the interactions with gas molecules during gas separation procedures. In principle, a sod cage with mesoporous β-cavities can be built by closing the large hexagonal window while keeping the small square window open. Such modification to the sod cage can maintain exceptionally large β-cavities for improved adsorption meanwhile reduce the pore aperture size to below 7 Å for the efficient separation of mixtures. Therefore, it is anticipated that this approach can circumvent the issues arising from the trade-off between higher adsorption capacity and better selectivity of the respective adsorbents.

The pore-space-partition (PSP) approach conceived by Bu features the division of a large cage or channel space into smaller segments by inserting pore-partitioning agents. The PSP approach significantly increases the stability of the framework and improves gas adsorption and separation. The C₃ symmetry of 2,4,6-trie(4-pyridyl)-1,3,5-triazine (tpt) ligand is often used as a pore-partitioning ligand that can be arranged within the windows of various crystalline molecular cages or cage-based MOFs.

In this study, an alternative strategy based on the window-space-directed assembly (WSDA) approach is proposed; herein, the windows of the large cage are partially blocked to afford ultramicropore apertures and enhance the host-guest interactions that exist between the host frameworks and the guest molecules. As a proof-of-concept, we designed and synthesized a series of mixed-linker ST-based sod-topology MOFs [Mₓ(OH/O)₆H₂O]btc₃[tpt]ₓ (sod-MOFs) containing 1,3,5-benzenetricarboxylate (btc), 2,4,6-tri(4-pyridyl)-1,3,5-triazine (tpt), homometallic trimer clusters (Mₓ) such as Co₃ (sod-Co) and Ni₃ (sod-Ni), and a heterometallic trimer cluster composed of Co₂Ti (sod-Co/Ti); the MOFs generated featured ultramicroporous square windows and a mesoporous sod cage. In these MOFs, STs serve as corner-sharing SBBs to produce a sod net topology, and the paired tpt ligands act as window-space-directing agents located on the large hexagonal windows of the sod cage. Notably, the mesoporous ST-sod-Co/Ti product exhibited high thermal/chemical stability and demonstrated good performance in the separation of acetylene from carbon dioxide.

**Results and discussion**

The synthesis of the ST-sod-MOFs series were conducted by mixing of inorganic salts (CoSO₄·7H₂O or Ni(NO₃)₂·6H₂O or CoCl₂·6H₂O and Cp₂TiCl₂) btc, and tpt with a 9 : 2 : 6 stoichiometric ratio under solvothermal reaction. All three compounds are isosctructural frameworks with homo- or heterometallic trimer clusters. The introduction of highly charged Ti⁴⁺ metals in the metal trimers is anticipated to render high thermal and chemical stability due to thermodynamic parameters. The use of tetravalent Ti⁴⁺ precursor and divalent Co²⁺ precursor afforded heterometallic [Co₂Ti₃µ₋₃(OH)₂(btc)₅(tpt)₇] (sod-Co/Ti) clusters, which were determined by site occupancy refinement and further confirmed by energy dispersive X-ray spectroscopy analysis with the Co/Ti molar ratio (2 : 1) (Fig. S6). The [Co₃(OH/(H₂O)(btc)₃(tpt)₁] (sod-Co) is discussed in detail here (Fig. 1). The SCXRD data analysis revealed that ST-sod-Co crystallized in the cubic space group Im3m. The lattice parameter of a = b = c = 33.2828(3) Å was much longer than that of ZIF-8 (ca. 16.9910(1) Å). The secondary building units of ST-sod-Co are classic cobalt trimers [Co₃(OH)(COO)₆] that are connected by four btc ligands to form a ST with a cavity diameter of approximately 4.8 Å; here, the metal trimers and btc ligands were located at the vertices and four faces, respectively (Fig. 1b). The corner-sharing approach caused the STs to assemble into a three-periodic zeolitic sod topology framework featuring a large truncated octahedral sod cage with a diameter of about 22 Å (Fig. 1c and 2c) that is almost double the size of that observed in ZIF-8 (ca. 11.6 Å). Additionally, the large hexagonal windows of the sod cages were occupied by π–π interaction paired tpt ligands, thereby leaving the relatively smaller square windows open (Fig. 1d, 2a and b). The large β-cavities are accessible via six square windows with ultramicroporous aperture dimensions of 5.57 × 5.57 Å² (Fig. 2a). Thus, the overall structure of ST-sod-Co could be viewed as close-packed, large truncated octahedral sod cages, each of which possessed eight closed hexagonal windows and six open square windows (Fig. 1d and e).

From a topological viewpoint, the [Co₃(OH)(COO)₆] clusters and the ligands (btc and tpt) could be reduced to yield 8-, 3-, 3-connected nodes, respectively. As a result, the entire ST-sod-Co framework could be defined as a very rare trinodal (3,3,8)-
connected network with the point symbol \((4^3\cdot6^3\cdot3^6\cdot15^2)\) (Fig. S4†). However, this initial simplification cannot clearly explain the entire structure of ST-sod-Co. Alternatively, we could ignore the pair of staggered tpt ligands and consider the four cobalt trimers connected via four btc ligands as the crux for ST formation, which was subsequently linked to the other STs in a corner-sharing fashion; as a result, the topology of the sod zeolitic network could be represented as \((4^2\cdot6^3)\) (Fig. 1d and S5†). To the best of our knowledge, this is the first example of a sod zeolitic network using corner-sharing, metal trimer-based supertetrahedra.39,40

For a better understanding of the role of tpt ligand on the assembly, a series of prototypical zeolitic ST-sod-MOFs were prepared. Like MIL-100 materials, the metal trimers are interconnected by the tricarboxylate linkers located in the faces to form ST, that extend into a three-dimensional zeolitic mtn topology with pentagonal and hexagonal pore windows. We also tried best to utilize such only ST vertices to obtain sod type MOFs with all open windows but without success. The reactions were carried out using the same protocol but without the use of tpt ligand; the self-assembly of single inorganic salt CoSO_4\(\cdot7\)H_2O or Ni(NO_3)_2\(\cdot6\)H_2O and btc ligand led to the formation of unknown crystalline phases (Fig. S10†); while using mixed inorganic salts CoCl_2\(\cdot6\)H_2O and Cp_2TiCl_2 with btc ligand produced a previously reported porous Co-BTC framework without Ti^4+ cations (Fig. S11†). These experiments suggest that there appears to be a dominant structure-determining driving force of a pair of staggered tpt ligands acting as the window-space-directed agent leading to the formation of zeolitic mesoporous ST-sod-MOFs.

Thermogravimetric analysis revealed that ST-sod-Co, ST-sod-Ni, and ST-sod-Co/Ti were thermally stable up to 320, 350, and 380 °C in N_2 stream, respectively (Fig. S15†). Furthermore, \textit{in situ} variable-temperature PXRD patterns of ST-sod-Ni and ST-sod-Co/Ti under air confirmed the maintenance of their
framework integrity up to 300 and 320 °C, respectively (Fig. S12†). The higher thermal stability of ST-sod-Co/Ti was probably due to the presence of stronger Ti(IV)–O coordination bonds. The phase purities of the ST-sod-MOFs were confirmed via PXRD (Fig. S13†), which was also employed to assess the chemical stability of samples treated in water, hydrochloric acid solution (pH = 2), and sodium hydroxide solution (pH = 12) at 25 and 100 °C for 24 h. Notably, the PXRD patterns of ST-sod-Co/Ti remained intact after various treatments and were in good agreement with the calculated patterns obtained from single crystal data, indicating the retention of crystallinity and structural integrity of ST-sod-Co/Ti (Fig. 3a and b). In addition, the stability of ST-sod-Co/Ti was also confirmed by N2 adsorption measurements. The adsorption capacities after water treatment under different conditions showed negligible changes as compared to the pristine sample (Fig. 3c). These results suggested that the Ti4+/Co2+ cooperative crystallization strategy increased the resistance of the framework against hydrolysis. Similar features have also been reported in heterometallic crystalline porous materials.19,20,35

The porosity of the ST-sod-MOFs was assessed by performing N2 sorption measurements at 77 K (Fig. 3d). Both the adsorption and desorption curves of all samples exhibited a reversible Type-I adsorption behavior with a stepwise N2 adsorption isotherm, which is indicative of a mesoporous cage in the framework.42 The saturated uptake values of 376, 400, and 457 cm3 g−1 were obtained for ST-sod-Co, ST-sod-Ni, and ST-sod-Co/Ti, respectively, with corresponding BET surface areas of 1767, 1783, and 2362 m2 g−1, respectively (Fig. S16–S18†). In particular, the BET surface area of ST-sod-Co/Ti was superior to those of other sod-type MOFs such as ZIF-8,5,26 IFMC-1,41 TTF-4,44 CPM-8S,40 and M-BTT (M = Mn, Fe, Co, Cu, Cd; BTT = 1,3,5-benzenetris(triazolyl)).46 The value is also slightly larger than those of well-known ST-based porous materials such as MIL-143,21 CAU-42,24 PCN-777,47 MOF-808,48 MOF-818,49 and sphMOF-4.50 The pore volumes of ST-sod-Co, ST-sod-Ni, and T-sod-Co/Ti were as 0.62, 0.62, and 0.71 cm3 g−1, respectively, which were in good agreement with the corresponding theoretical values of 0.65, 0.73, and 0.65 cm3 g−1, respectively, calculated using the PLATON program. Furthermore, the pore size distributions of the ST-sod-MOFs were calculated using the Horváth–Kawazoe (H–K) model assuming the sphere pore geometry, whose result indicates two types of pores with diameters of approximately 5.0 and 22.0 Å (Fig. 3d). These calculated values were in agreement with the effective cavity diameters of the small tetrahedral cage and the large truncated octahedral cage, respectively, as observed in the crystal structure via SCXRD.

The permanent porosity and distinctive cage structure of the three isostructural MOFs in this study encouraged us to examine their selective gas adsorption performance toward acetylene (C2H2), ethane (C2H6), ethylene (C2H4), carbon dioxide (CO2), and methane (CH4). First, single-component adsorption isotherms of the five gases were obtained at 273 and 298 K, where the adsorption capacities of all three isostructural MOFs followed the trend of C2H2 > C2H6 > C2H4 > CO2 ≈ CH4 under the same conditions (Fig. S19–S21†).

Considering that the removal of CO2 impurities to obtain high-purity C2H2 is highly desirable in industrial applications, the process of C2H2/CO2 separation is an important albeit difficult industrial separation process because of the
similarities in molecular size and physicochemical characteristics of C\textsubscript{2}H\textsubscript{2} and CO\textsubscript{2}. Fig. 4 shows the results of separation using ST-sod-Co/Ti, which was chosen from the three MOF types examined because it exhibited the highest BET surface area and thermal/chemical stability. The adsorption capacity values of ST-sod-Co/Ti for C\textsubscript{2}H\textsubscript{2} and CO\textsubscript{2} at 1.0 bar and 273 K were 105 and 72 cm\textsuperscript{3} g\textsuperscript{-1}, respectively, at 298 K and 1.0 bar, these values were 57 and 40 cm\textsuperscript{3} g\textsuperscript{-1}, respectively (Fig. 4a). The resulting C\textsubscript{2}H\textsubscript{2}/CO\textsubscript{2} uptake ratio of 1.42 for ST-sod-Co/Ti at 298 K and 1.0 bar was comparable to the results obtained for UTSA-74a (1.52)\textsuperscript{23} and higher than those of benchmark MOFs such as TIFSIX-2-Cu-i (0.95),\textsuperscript{23} SIFSIX-3-Ni (1.2),\textsuperscript{24} and KMOF-1-Ni (1.19)\textsuperscript{25} under the same conditions. The adsorption selectivity of ST-sod-Co/Ti for equimolar binary C\textsubscript{2}H\textsubscript{2}/CO\textsubscript{2} gas mixtures was evaluated using the ideal adsorbed solution theory based on a single-site Langmuir–Freundlich simulation on the pure-component isotherms of C\textsubscript{2}H\textsubscript{2} and CO\textsubscript{2} at 273 and 298 K (Fig. 4b). The adsorption selectivity value of ST-sod-Co/Ti at 298 K was 2.66 at 0.01 bar, which decreased with increasing pressure to 1.65 at 1.0 bar. We noted that the C\textsubscript{2}H\textsubscript{2}/CO\textsubscript{2} selectivity value of 1.65 for ST-sod-Co/Ti at 298 K and 1.0 bar was lower than those of prototypic MOFs such as FJU-90 (4.3),\textsuperscript{24} TIFSIX-2-Cu-i (6.5),\textsuperscript{23} and UTSA-74a (9.0),\textsuperscript{23} but was comparable to that of Zn-MOF-74 (2.0)\textsuperscript{23} under similar conditions. The adsorption isotherms of C\textsubscript{2}H\textsubscript{2} and CO\textsubscript{2} at 273 and 298 K were fitted using the virial equation (Fig. S22–S27), and the isosteric heat (Q\textsubscript{st}) was calculated using the Clausius–Clapeyron equation. The zero-coverage Q\textsubscript{st} value of C\textsubscript{2}H\textsubscript{2} for ST-sod-Co/Ti was calculated to be 42.4 kJ mol\textsuperscript{-1}, which was much larger than that for CO\textsubscript{2} of 33.6 kJ mol\textsuperscript{-1} (Fig. S28). This discrepancy between the Q\textsubscript{st} values may be attributed to the synergistic effects exerted by the ultramicroporous apertures, the open metal sites, and the uncoordinated triazine N-atoms lined on the pores surfaces. Notably, the zero-coverage Q\textsubscript{st} value for C\textsubscript{2}H\textsubscript{2} in ST-sod-Co/Ti (42.4 kJ mol\textsuperscript{-1}) was at the higher end of the scale for MOF-based solid adsorbents (>40 kJ mol\textsuperscript{-1})\textsuperscript{25} and was much higher than those observed for ST-sod-Ni (25.2 kJ mol\textsuperscript{-1}) and ST-sod-Co (29.1 kJ mol\textsuperscript{-1}) as well as the values associated with many other benchmark MOFs, including UTSA-74a (32 kJ mol\textsuperscript{-1}),\textsuperscript{25} JCM-1 (36.9 kJ mol\textsuperscript{-1}),\textsuperscript{55} and DICRO-4-Ni-i (37.7 kJ mol\textsuperscript{-1}),\textsuperscript{57} albeit significant lower than an acetylene nanotrap Cu-ATC (79.1 kJ mol\textsuperscript{-1}) reported very recently.\textsuperscript{54} However, the Q\textsubscript{st} value for CO\textsubscript{2} in ST-sod-Co/Ti (33.6 kJ mol\textsuperscript{-1}) was similar to that observed for ST-sod-Ni (31.1 kJ mol\textsuperscript{-1}), ST-sod-Co (32.1 kJ mol\textsuperscript{-1}), JCM-1 (33.4 kJ mol\textsuperscript{-1}),\textsuperscript{56} and DICRO-4-Ni-i (33.9 kJ mol\textsuperscript{-1}).\textsuperscript{57} These results showed that there were more extensive interactions with C\textsubscript{2}H\textsubscript{2} than CO\textsubscript{2}, thereby rendering the potential application of ST-sod-Co/Ti for C\textsubscript{2}H\textsubscript{2}/CO\textsubscript{2} separation.

The C\textsubscript{2}H\textsubscript{2}/CO\textsubscript{2} separation capability of ST-sod-Co/Ti in practical applications was investigated via mixed-gas breakthrough experiments conducted at 298 K. In these breakthrough experiments, a mixed gas of C\textsubscript{2}H\textsubscript{2}/CO\textsubscript{2} (50 : 50, v/v) at a total flow of 1 mL min\textsuperscript{-1} was injected into a column packed with activated ST-sod-Co/Ti. The resulting breakthrough curve indicated that the CO\textsubscript{2} gas was the first eluted through the packed column after about 36.6 min g\textsuperscript{-1}, whereas the C\textsubscript{2}H\textsubscript{2} gas was not detected until 42.5 min g\textsuperscript{-1} (Fig. 4c). This result

![Fig. 4](image-url) (a) Single-component gas adsorption isotherms for C\textsubscript{2}H\textsubscript{2} and CO\textsubscript{2} of ST-sod-Co/Ti measured at 273 K and 298 K. (b) IAST calculations of C\textsubscript{2}H\textsubscript{2}/CO\textsubscript{2} adsorption selectivity for ST-sod-Co/Ti at 273 K and 298 K. (c) Experimental column breakthrough curves of ST-sod-Co/Ti for an equimolar C\textsubscript{2}H\textsubscript{2}/CO\textsubscript{2} mixture at 298 K and 1.0 bar. (d) The cycling test of an equimolar C\textsubscript{2}H\textsubscript{2}/CO\textsubscript{2} mixture at 298 K and 1.0 bar.
demonstrated that activated ST-sod-Co/Ti could effectively capture C₂H₂ from an equimolar C₂H₂/CO₂ mixture via a packed column. Furthermore, the stability and recyclability of activated ST-sod-Co/Ti were examined using recycling breakthrough experiments. As shown in Fig. 4d, the activated ST-sod-Co/Ti was reusable for four cycles with no loss in its adsorption capacity, indicating that the MOF exhibited good regenerability for C₂H₂/CO₂ separation. Thus, ST-sod-Co/Ti holds some promise for the challenging application of C₂H₂/CO₂ separation.

Conclusions

In conclusion, we present a novel window-space-directed assembly strategy for the synthesis of zeolitic mesoporous MOFs with ultramicroporous apertures based on super-tetrahedral building units. Three isostructural ST-based ST-sod-MOFs, namely, ST-sod-Co, ST-sod-Ni, and ST-sod-Co/Ti, with homo- or heterometallic trimers were fabricated and characterized via SCXRD. Notably, the ST-sod-MOFs possessed a sod topology whose STs served as nodes. In these ST-sod-MOFs, the large β-cavity mesoporous pores (~22 Å diameter) were accessible via six square windows with ultramicroporous apertures (~5.6 Å diameter), whereas their eight hexagonal windows were closed by the paired tpt ligands acting as window-space-directed agents. Remarkably, ST-sod-Co/Ti exhibited good thermal stability, high acid/base-proof stability, and the ability to effectively separate C₂H₂/CO₂ mixtures. Like other heterometallic MOFs with variable metal trimers, this ST-sod-MOFs platform also exhibited enhanced chemical and functional complexity by tuning the metal cations. Thus, our study provides an effective and innovative strategy for building ST-based zeolitic mesoporous MOFs with ultramicroporous apertures and paves the way for the future design and synthesis of functional, highly connected materials for various applications.

Author contributions

L. Z., C. L., and S. M conceived the research. H. Y. synthesized samples. L. Z., F. L., J. Y., N. H., Q. W., and J. S., performed the syntheses and structural characterizations of MOFs. W. C., W. W., X. W., W. Y. and D. Y. performed the gas sorption and breakthrough experiments. Y. L. performed the SEM characterizations. L. Z. A. N., A. M. A. and S. M. wrote the manuscript. All authors contributed to the discussion.
