(Dated: March 21, 2022)

We present a comparative numerical study of the ordered and the random two-dimensional sine-Gordon models on a lattice. We analytically compute the main features of the expected high temperature phase of both models, described by the Edwards-Wilkinson equation. We then use those results to locate the transition temperatures of both models in our Langevin dynamics simulations. We show that our results reconcile previous contradictory numerical works concerning the superroughening transition in the random sine-Gordon model. We also find evidence supporting the existence of two different low temperature phases for the disordered model. We discuss our results in view of the different analytical predictions available and comment on the nature of these two putative phases.

I. INTRODUCTION

The location and characteristics of phase transitions in disordered media constitute a long-standing and controversial question, particularly in more than one spatial dimension [1]. The question becomes even more difficult if the disorder is not very weak; then, new, non-trivial behavior is commonly found, involving features such as aging, ergodicity breaking, extremely slow dynamics, complicated energy landscapes, etc.; major examples of this are spin glasses and structural glasses [1, 2]. In this context, the properties of crystal surfaces growing on disordered substrates, frequently described by a two-dimensional random-phase sine-Gordon model (RsGM), have attracted a lot of attention in the last decade [3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22]. Interestingly, the same model describes many other relevant physical problems, such as randomly pinned flux lines confined in a plane [5, 21, 23, 24, 25], vortex lines in planar Josephson junctions [26], charge density waves [27], and commensurate-incommensurate transitions [28].

In spite of those efforts, the phase diagram and main features of the RsGM are not clear yet. To summarize what is known, we refer for comparison to the ordered sine-Gordon model (OsGM), which is rather well understood (see, e.g., [1, 24, 25, 31, 32, 33] and references therein). The Hamiltonian for the OsGM is

\[
H = \sum_r \left[ \frac{1}{2} \sum_{n.n.} |h(r) - h(r')|^2 + V_0 \left( 1 - \cos[h(r) - h^{(0)}(r)] \right) \right].
\]

where \( n.n. \) stands for the nearest neighbors of site \( r \). The OsGM corresponds to \( h^{(0)}(r) \equiv 0 \), whereas the RsGM is defined by choosing the quenched disorder variables \( h^{(0)}(r) \) randomly from a uniform distribution in \([0,2\pi] \). We will discuss our work in terms of growth on flat (OsGM) or disordered (RsGM) substrates (see [24, 25, 22, 24, 28] for other physical interpretations): Accordingly, \( h(r) \) is a continuous variable representing the height of the growing surface at site \( r \) of the lattice, and the cosine term is a potential energy making integer (i.e., multiples of the crystalline lattice constant) values of the height energetically favorable. We will consider two-dimensional (2D) square lattices, i.e., \( r = (r_1, r_2) \), with \( N = L \times L \) sites. As first shown by Chui and Weeks [34] (see also [35]) by means of a renormalization group (RG) approach [36], the OsGM possesses a Kosterlitz-Thouless [37] type topological transition between a low temperature, flat phase and a high temperature, rough phase, the latter being described by the Edwards-Wilkinson (EW) equation [38], i.e., the diffusion equation with additive white noise (see below). Above the so called roughening temperature \( (T_R) \), thermal fluctuations effectively suppress the effect of the cosine potential, and the surface becomes free, described only by the kinetic part of the Hamiltonian (1). As will be shown below, the most im-
important measurable consequence of this is that the width of the interface,
\[ w^2 = \frac{1}{N} \sum_r (h(r) - \bar{h})^2, \quad \bar{h} = \frac{1}{N} \sum_r h(r), \quad (2) \]
scales (in 2D) as \( w^2 \sim \ln L \) in the asymptotic regime.

In contrast with the clear picture for the OsGM, there are very few generally accepted results for the RsGM. One of them is that there must be a roughening temperature above which the potential effectively vanishes (much as in the case of the OsGM) leading to EW behavior. Apart from this, there is indeed a superrough low temperature phase in both the OsGM and the RsGM, beginning with \( V_0 = 1 \) and \( \epsilon = 2\pi \) and subsequently analyzing the model behavior for different \( V_0 \) and \( \epsilon \). Finally, in Sec. IV we present and discuss our conclusions and indicate future directions.

In this paper, we attempt to shed light on these issues by simultaneously studying the OsGM and the RsGM in different regions of their phase diagram. As we will show below, it turns out that the potential strength, \( V_0 \), crucially determines the model features. In addition, it is also natural to ask about the **intensity of the disorder**: How does the model phenomenology change if the disorder intensity varies in \([0, \epsilon]\) with \( \epsilon < 2\pi \)? The importance of these points can be clearly seen in the Langevin equation,
\[ \frac{\partial h(r, t)}{\partial t} = \nabla^2 h(r, t) - V_0 \sin[h(r, t) - h^{(0)}(r)] + \eta(r, t), \quad \eta(r, t), \quad (3) \]
and changing variables according to \( \tilde{h}(r, t) = h(r, t) - h^{(0)}(r) \) (i.e., the height referred to the substrate), we find
\[ \frac{\partial \tilde{h}(r, t)}{\partial t} = \epsilon \tilde{F}(r) + \nabla^2 \tilde{h}(r, t) - V_0 \sin(\tilde{h}(r, t)) + \eta(r, t) \]
where \( F(r) = \nabla^2 h^{(0)}(r)/\epsilon \). In this form, the disorder is a random (correlated in space) chemical potential acting on a surface growing on a flat substrate. If we think of the roughening transition for the OsGM in terms of the interplay between the temperature \( T \) and the energy scale introduced by the potential, \( V_0 \), when \( \epsilon \neq 0 \), we have another energy scale, \( \epsilon \), which can modify the universal features of the roughening transition or even give rise to novel thermodynamical transitions.

Having the above issues in mind, we discuss our work according to the following scheme: Section II presents an analytical study of the EW equation and other statistical mechanics results about the energy and roughness. Section III deals with the main part of our work, namely Langevin dynamics simulations of the OsGM and the RsGM, beginning with \( V_0 = 1 \) and \( \epsilon = 2\pi \) and subsequently analyzing the model behavior for different \( V_0 \) and \( \epsilon \). Finally, in Sec. IV we present and discuss our conclusions and indicate future directions.

II. ANALYTICAL RESULTS

**A Linear theory: The Edwards-Wilkinson equation**

According to the RG approach \[29\], the high temperature phase of the OsGM obeys the EW equation \[23\],
\[ \frac{\partial h(r, t)}{\partial t} = \nabla^2 h(r, t) + \eta(r, t). \quad (7) \]
Equation \[7\] can be solved by means of the Fourier decomposition (see \[32\] for details),
\[ \hat{h}_q = \frac{1}{L} \sum_r e^{iqr} h(r, t), \quad (8) \]
where \( q = \frac{2\pi}{L} k \), \( k_i = 0, \ldots, L-1 \) is the reciprocal vector. The structure factor can then be shown to be
\[ S(q) = \langle \hat{h}_q \hat{h}_{-q} \rangle = T \frac{1 - e^{-2\omega_q t}}{\omega_q}, \quad (9) \]
\( \omega_q \) being the 2D EW discrete dispersion relation
\[
\omega_q = 4 \sin^2 \left( \frac{q_1}{2} \right) + 4 \sin^2 \left( \frac{q_2}{2} \right).
\]  
(10)

From \( S(q) \) we can obtain the relevant magnitudes, such as the total roughness
\[
w^2(t) = \frac{1}{L^d} \sum_{q \neq 0} [h(r, t) - h]\]  
= \frac{1}{L^d} \sum_{q \neq 0} S(q),
\]  
(11)

the correlation function,
\[
C(r) = \left( \frac{1}{L^d} \sum_s [h(s + r) - h(s)]^2 \right)
= \frac{2}{L^d} \sum_q S(q)[1 - \cos(q \cdot r)],
\]  
(12)

the total slope,
\[
s^2(t) = \frac{1}{L^d} \sum_{q \neq 0} S(q) \omega_q,
\]  
(13)

and the slope difference correlation function,
\[
G(r) = \left( \frac{1}{L^d} \sum_s [\nabla h(s + r) - \nabla h(s)]^2 \right)
= \frac{4}{L^d} \sum_q S(q) \sum_{i=1}^2 [1 - \cos(q_i r_i)] [1 - \cos(q_i)].
\]  
(14)

From Eq. (3) we can find an estimate for the time needed to reach saturation, \( t_x \), and the dynamic exponent, \( z \): We compute the time that the structure factor needs to be within 1% of its saturated form for the slowest Fourier mode, that with the lowest \( |q|, |q| = 2\pi/L \):
\[
t_x \simeq 3 \times 10^{-2} L^2,
\]  
(15)
implying \( z = 2 \). For the saturated roughness, we obtain
\[
w^2(t \to \infty, L) = \frac{T}{4 L^2} \sum_{k_1, k_2=1}^{L-1} \left[ \sin^2 \left( \frac{q_1}{2} \right) + \sin^2 \left( \frac{q_2}{2} \right) \right]^{-1},
\]  
(16)

which cannot be computed exactly but, for large \( L \), can be approximated changing the sum by an integral and the sine functions by their arguments, arriving at
\[
w^2(t \to \infty, L) \simeq \frac{1}{(2\pi)^2} \int_{2\pi/L}^{2\pi} dq_1 dq_2 \frac{T}{(q_1^2 + q_2^2)} \simeq \frac{T}{2\pi} \int_{2\pi/L}^{2\pi} dq = \frac{T}{2\pi} \ln L,
\]  
(17)
yielding a roughness exponent \( \alpha = 0 \). As for the total slope, it tends to a value independent of \( L \),
\[
s^2 \simeq T,
\]  
(18)

whereas for the correlation functions, we find for large \( r \)
\[
C(r) \simeq \frac{T}{r} \ln r,
\]  
(19)
\[
G(r) \simeq \frac{2s^2 + T}{4\pi} \ln \frac{r^8}{[(r^2 + 1)^2 - 4r_1^2][(r^2 + 1)^2 - 4r_2^2]} \simeq 2T.
\]  
(20)

B Other results for the energy and the roughness

At equilibrium, the partition function for the OsGM is
\[
Z = \int \left[ \prod_r dh(r) \right] e^{-\beta \sum_r \langle \nabla h(r) \rangle^2 + V_0(1 - \cos h(r))},
\]  
(21)

where \( \beta = T^{-1} \). Expanding for high temperatures [41] means rewriting Eq. (21) as a series in powers of \( \beta V_0 \):
\[
Z = \sum_{n=0}^{\infty} \frac{\beta V_0^n}{n!} \int \left[ \prod_r dh(r) \right] e^{-\beta \sum_r \frac{1}{2} \langle \nabla h(r) \rangle^2} \times \left( \sum_r \cos h(r) \right)^n = Z_0 \sum_{n=0}^{\infty} \frac{\beta V_0^n}{n!} \left( \sum_r \cos h(r) \right)^n |_{H_0},
\]  
(22)

where \( Z_0 \) is the partition function of \( H_0 \), the free hamiltonian [i.e., Eq. (1) without the potential term]. By means of this expansion we obtain
\[
\langle \cos h(r') \rangle_H = \frac{Z_0}{Z} \sum_{n=0}^{\infty} \frac{\beta V_0^n}{n!} \times \left( \sum_r \cos h(r) \right)^n |_{H_0}.
\]  
(23)

where subdominant terms such as \( \beta^n \exp(-A/\beta) \) have been neglected, and only terms of the order \( \beta^n \) have been kept. The expression above can be put in the form
\[
\langle \cos h(r') \rangle_H = \frac{Z_0}{Z} \sum_{n=0}^{\infty} \frac{2^{2n-1} (n!)^2}{n!(\beta V_0)^{2n-1}} \times \left( \sum_{n=0}^{\infty} \frac{\beta V_0^{2n}}{2^{2n}(n!)^2} \right)^{-1} = \frac{\beta V_0}{2} - \frac{(\beta V_0)^3}{16} + \frac{(\beta V_0)^5}{96} - O((\beta V_0)^7),
\]  
(24)
yielding for the approximate energy per site
\[
E = \frac{1}{L^2} \langle H \rangle = \frac{1}{2\beta} + V_0 \left( 1 - \frac{\beta V_0}{2} + \frac{(\beta V_0)^3}{16} + O((\beta V_0)^5) \right).
\]  
(25)
For the roughness, we have to compute

$$\langle (h(r) - \bar{h})^2 \rangle_H = \frac{Z_0}{Z} \times \sum_{n=0}^{\infty} \frac{(\beta V_0)^n}{n!} \left\langle h^2(r) \sum_{r'} \cos(h(r'))^n \right\rangle_{H_0},$$

assuming that at equilibrium $\bar{h} = 0$. Neglecting again subdominant terms, we find

$$\langle h^2(r) \rangle_H = \frac{Z_0}{Z} \langle h^2(r) \rangle_{H_0},$$

and hence

$$w_H^2 = w_{H_0}^2 (1 - \frac{\beta V_0}{4} + \frac{3(\beta V_0)^2}{64} - \frac{19(\beta V_0)^3}{2304} + O((\beta V_0)^4)).$$

Finally, at low temperatures the height exhibits only small deviations from $h = 0$, and therefore we can approximate the Hamiltonian as

$$H = \sum \frac{1}{2} (\nabla h(r))^2 + V_0 [1 - \cos(h(r))],$$

$$\simeq \sum \frac{1}{2} (\nabla h(r))^2 + V_0 \frac{h(r)^2}{2},$$

i.e., $2N$ quadratic terms, each one of which, according to the equipartition theorem, contributes with $T/2$ to the energy value. Taking into account the global factor $1/2$, we conclude that at low temperatures the energy of the OsGM is approximately $E = T/2$.

III. LANGEVIN DYNAMICS RESULTS

A Numerical simulation details

We have integrated the Langevin equation corresponding to the Hamiltonian with $V_0 = 1$, on $L \times L$ square lattices with periodic boundary conditions, using a stochastic second order Runge-Kutta method; in some cases, we have repeated the simulations with a Heun method, with excellent agreement between both procedures. We are therefore sure that our results are not an artifact of our numerical method, a conclusion further reinforced by the agreement with the theoretical expectations of the previous section as we discuss below. The simulations reported in this paper were carried out with a time step $\Delta t = 0.01$ on lattices of sizes $L = 64, 128$ and 256. It is important to stress that we did not perform averages over the quenched noise in the RsGM; however, we checked that the outcome of our simulations did not depend strongly on the realization of the quenched noise or the initial conditions (flat, $h(r) = 0$; as the substrate, $h(r) = h^{(0)}(r)$, or random) by repeating several times a number of our simulations. In all cases, simulations consisted of an equilibration time and a measuring period. Eq. (13) predicts that the time needed for equilibration is $t_e \approx 500$ for $L = 128$ and $t_e \approx 2000$ for $L = 256$, and hence we used equilibration times of 5000 and 10000 units, respectively; afterwards, we let the system evolve for an equal period, over which we performed thermal averages. Equilibration was ensured in all cases by verifying that the fluctuations of the energy were Gaussian and by checking the equality of the specific heat computed from those fluctuations and from derivatives of the mean energy, as well as by monitoring the evolution in time of the quantities of interest toward a stationary state. As an additional test, we compared the imposed simulation temperature, arising from the noise term, to that measured during the evolution according to the equipartition theorem; both quantities were always found to agree within a 0.1%. Finally, we did a few very longer runs, whose outcome agreed with that of the shorter runs.

B Standard RsGM: $V_0 = 1$ and $\epsilon = 2\pi$

We begin by discussing our results for the “canonical” version of both the OsGM and the RsGM, i.e., Hamiltonian with $V_0 = 1$, as studied (for the ordered case) in Shugard et al. Both quantities were always found to agree within a 0.1%. Finally, we did a few very longer runs, whose outcome agreed with that of the shorter runs.

The first quantity we discuss, shown in Fig. 1, is the mean energy of both models. As we see, the results are largely independent of the system size, and hence it is unlikely that they are affected by finite size effects. The plot shows that the mean energy of the OsGM reaches the high temperature approximation at $T_0 = 16 \pm 1$; on the other hand, the mean energy for the RsGM is never too far from it, although for temperatures lower than $T_1 = 4 \pm 1$ the numerical values lie slightly below the
high temperature result. At temperatures higher than $T_0$ the energies of both models coincide within the accuracy of our simulations. These results suggest that $T_0$ could be the roughening temperature, $T_R$, for the OsGM and $T_1$ the superrighening temperature, $T_{SR}$, for the RsGM, because the EW behavior of the mean energy of both models indicates the effective supression of the sine term by temperature. The inset in Fig. 4 presents the specific heat, $C_v$, of both models, exhibiting a well defined peak in $C_v$ for the OsGM with its maximum at temperature $T = 9$, much lower than $T_0$. In contrast, we do not observe any peak for the RsGM; there might be a peak at $T = 3$, but the evidence is not conclusive. Concerning the peak for the OsGM, we stress again the absence of any finite size effect, consistent with a KT type transition. Furthermore, we believe that this peak is a (Schottky) 

\textit{anomaly} \cite{28} similar to that observed in 2D XY and easy-plane Heisenberg spin models \cite{29} above the KT transition. Recall that when mapping the OsGM to the XY model the temperature of the former maps to the inverse temperature of the latter \cite{30}, hence the observation of the anomaly below the possible transition temperature $T_0$. This reinforces our interpretation of $T_0$ as the roughening temperature of the OsGM.

The total roughness of both models, shown in Fig. 3, behaves similarly for temperatures higher than $T_0$, depending linearly on temperature. In both cases, we see that the slope of the roughness depends on the system size, as predicted by Eq. (16). Whereas the approximation in Eq. (17) expression yields slopes 0.66 and 0.77 for $L = 64$ and 128, respectively, if we numerically compute the exact result, Eq. (11), the slopes turn out to be 0.71 and 0.82, in excellent agreement with the results of our simulations. Below $T_0$, the roughness for the OsGM is independent of the system size and depends nonlinearly on temperature, whereas above $T_0$ we find linear dependence on temperature and clear finite size effects. For the RsGM, the linear behavior extends all the way down to $T_1$, and below $T_1$ the behavior becomes nonlinear. The slope of the linear region is approximately the same in the first part, from $T_1$ to $T_0$, and in the second, above $T_0$, i.e., the whole linear region is well described by the EW model. This means that above $T_0$ the linear model describes accurately the behavior of the OsGM, and hence from now on we identify $T_0$ with the roughening temperature $T_R$, whereas for the RsGM, the same is true of $T_1$ and $T_{SR}$. Figure 3 presents also results for the roughness susceptibility, $\chi_w$, defined as $\chi_w = \langle (w^2)^2 \rangle - \langle w^2 \rangle^2 / T^2$. For the OsGM, $\chi_w$ exhibits a very clear peak at $T_R$, and above $T_R$ it is the same as for the RsGM; however, this magnitude is very noisy and these results must be taken with caution. In fact, one could identify a peak for the RsGM at $T_{SR}$, but different realizations lead to different results, in contrast with the peak for the OsGM, which is the same for all realizations. Below $T_R$, the values of $\chi_w$ for the OsGM are independent of the system size, whereas above $T_R$ they increase with size without any definite scaling.

Figure 3 depicts the height-difference correlation function for the two studied models, and shows that above $T_R = T_0$ and $T_{SR} = T_1$ they behave as predicted by the linear theory: The slope of the numerical height-difference correlation function is 0.32, indistinguishable from the predicted 0.318 by Eq. (13). In addition, the correlation functions for the OsGM and the RsGM coincide, as shown in the plot for the RsGM. We see that the behavior of the correlation functions is in full agreement with our claims regarding $T_R$ and $T_{SR}$, and this is further confirmed by the plot of the slope correlation function in Fig. 4. It is important to note that, below $T_{SR}$, the behavior of the height difference correlation function for the RsGM is approximately a squared logarithm, as predicted by RG calculations. We postpone discussion of this point to the next section.

Finally we studied another magnitude, namely

$$m_1 = \langle \cos \left[ h(r) - h(0)(r) \right] \rangle. \quad (30)$$

For the OsGM this is the average computed in the preceding section, whereas for the RsGM it is the average of the cosine of the height referred to the substrate. Figure 5 shows our results: The high temperature approximation, Eq. (24), agrees very accurately with the simulations for temperatures above $T_R$ (OsGM) and $T_{SR}$ (RsGM). The results for both models are again indistinguishable for temperatures above $T_R$. Interestingly, $m_1$ is largely independent not only of the system size, but also on the realization of the quenched disorder for the RsGM.

### C Other potential strengths

We now turn to the question of the influence of the potential strength on the RsGM behavior. We have considered two representative values, $V_0 = 0.2$ and $V_0 = 5$, i.e., five times smaller and larger, respectively, than the “canonical” value $V_0 = 1$. The smallest value is close to that considered in \cite{31}, $V_0 = 0.15$, and we expect that our results will be comparable to theirs. As before, we begin by discussing the total roughness and the specific heat (see Fig. 3). First of all, for all values of $V_0$ there is a temperature above which the roughness value is independent of $V_0$ and of the presence or absence of disorder. This means that our identification of this regime with the effective suppression of any potential effect is indeed correct: Different $V_0$ leads only to different transition temperatures. Thus, for the OsGM we find $T_{R_{V0=0.2}} = 13 \pm 1$. For $V_0 = 5$ is indistinguishable from the predicted $T_{R_{V0=5}} = 19 \pm 1$, in agreement with the intuitive expectation that larger potentials need higher temperatures to be suppressed. Aside from this, the general shape of the roughness curve is basically the same for the three values of $V_0$. The situation (for the OsGM) is the same as far as the specific heat is concerned: Larger (smaller) $V_0$ leads to larger (smaller) anomalies, which are displaced to
higher (lower) $T$ following the corresponding $T_R$. Therefore, we conclude that changing $V_0$ does not introduce anything qualitatively new in the OsGM.

The picture for the RsGM is substantially different: Modifying $V_0$ does give rise to qualitatively new phenomena. Let us first look at the small $V_0$ case. Figure 6 shows that the roughness follows a straight line all the way down to $T = 0$ (although we cannot exclude that there are nonlinear effects for $T < 1$ with our present resolution). This would suggest that there is no transition in this case, very much like the results of Batrouni and Hwa [5]. The upper panel of Fig. 2 where the height difference correlation function is depicted, confirms this interpretation, showing no dependence on temperature in the analyzed range; Fig. 6 for $m_1$, agrees with this as well, in so far as the dependence of $m_1$ on temperature is well described by the high temperature expansion. In view of this, we can conclude that if there is a transition, it occurs at a temperature smaller than $T \approx 1$.

Finally, let us consider the large $V_0$ case, $V_0 = 5$. The plot of the roughness in Fig. 8 exhibits a striking peak for $T = 5$, after which the roughness decreases until reaching the high temperature regime (marked by the corresponding OsGM with the same value for $V_0$) at $T = 8 \pm 1$. To assess the relevance of this peak in the roughness, we repeated our simulations for $L = 64$ and performed additional ones for $L = 128$. The results, collected in Fig. 8, show that the peak is a realization dependent feature. However, in this plot we also see that for temperatures below $T = 5$ the roughness is roughly independent of the system size, something which we did not observe when $V_0 = 1$ (the lines for $V_0 = 1$ are included in Fig. 8 again for comparison). Hence, even if the peak at $T = 5$ does not actually exist, that temperature does seem to separate two different regions. In addition, for $V_0 = 5$ the specific heat has a (more smeared) maximum at about the same temperature as that of the roughness, although our data are much noisier and we cannot establish clearly the maximum temperature; the dependence, however, is manifestly non-monotonic. Figure 8 supports our conclusion that $T_{SR}^{-5} = 8 \pm 1$, whereas nothing special is seen as $m_1$ goes through $T = 5$, the roughness maximum. The most intriguing result is the one in Fig. 8 for the height difference correlation function: For $T \leq 5$, the scaled correlations decrease with temperature but, simultaneously, the correlation length increases, up to $T = 5$, when it increases beyond the system size. Above that temperature, it follows the same evolution as the $V_0 = 1$ case, finally reaching $T_{SR}^{-5} = 8 \pm 1$. Whereas in this intermediate temperature regime the height difference correlation functions are well described by squared logarithms, Fig. 6 immediately shows that the lowest temperature correlations can by no means be considered squared logarithms. This suggest the presence of a new phase transition at $T^* \approx 5 \pm 1$. We will discuss the possible nature of the low temperature phase and the existence of this transition in the next section.

D Other disorder strengths

We now generalize the RsGM and let $h^{(0)}(r)$ to be randomly chosen from a uniform distribution in $[0, \epsilon]$, with $0 < \epsilon < 2\pi$; $\epsilon = 2\pi$ is the case studied in the preceding Section. As representative examples we have considered $\epsilon = 0.8$ and $\epsilon = 0.2$, closer to the RsGM and the OsGM, respectively. From the roughness dependence on temperature, shown in Fig. 10, we see that for both values of $\epsilon$ the dependence of the roughness on temperature is qualitatively similar to the OsGM, the results for the lower $\epsilon$ value being practically the same as for the $\epsilon = 0$ case. However, the case $\epsilon = 0.8$ is somewhat different: The low temperature region appears to consist of two straight lines, changing slope at a temperature around $T^* = 5$, rather than a nonlinear dependence. By reasoning as above, we identify $T_{SR}^{\epsilon = 0.2} \approx T_R = 16 \pm 1$ and $T_{SR}^{\epsilon = 0.8} = 12 \pm 1$, values which are confirmed by the energy behavior (not shown), the height difference (Fig. 11) and slope (not shown) correlation functions, and by the dependence of $m_1$ on temperature (not shown).

An interesting question arises from Fig. 11: There is no evidence about the squared logarithmic behavior found for the RsGM and, furthermore, the plots exhibit a finite correlation length below $T_{SR}$ for both values of $\epsilon$. Another intriguing fact is the nonmonotonic dependence of the correlation function on temperature for $\epsilon = 0.8$: From the curve for $T = 1$, the scaled correlation function decreases up to $T = 5$; upon further increasing the temperature, the evolution of the curves is very similar to that of the OsGM. This might be connected with the change in slope in the roughness curve mentioned in the preceding paragraph (see Fig. 10), but we have not been able to draw a clearer connection. All this is clear evidence that the behavior of the RsGM is significantly dependent on the disorder strength.

IV. DISCUSSION AND CONCLUSIONS

Let us begin the discussion of the above results by analyzing our findings about the OsGM. Our simulations strongly support that $T_R = 16 \pm 1$ for the OsGM on a lattice with $V_0 = 1$. This is in contrast to the claims in [35, 36] that $T_R = 25$ where a different way of defining the transition, which assumes the validity of the RG approach, was used (see Sec. III B and [35, 36, 37, 38]). Further, the result is also in contrast with the RG prediction itself [35, 36, 37, 38, 39], which in our units is $T_R = 8\pi$. However, we believe that the comparison with the linear theory for the EW high temperature phase has a much more physical character while keeping the basic RG ideas, and establishes beyond doubt that for the studied lattices the roughening temperature is $T_R = 16 \pm 1$ for $V_0 = 1$. Another hint in favor of our claim is the finding of the (Schottky) anomaly in the specific heat, which should
Let us now turn to the RsGM. In the “canonical” case, \( V_0 = 1 \), we found a superroughening transition at \( T_{SR} = 4 \pm 1 = T_R / 4 \), to be compared to RG predictions that it should occur at \( T_R / 2 \). Below \( T_{SR} \), we have obtained a \( \ln^2 \) dependence of the height difference correlation function, in agreement with RG results. However, we have clearly shown that the superroughening transition depends on \( V_0 \), confirming the earlier report by Batrouni and Hwa \( \cite{8} \) on the absence of the transition in Langevin dynamics simulations for \( V_0 = 0.15 \), and later reports by Rieger \( \cite{10} \) and Ruiz-Lorenzo \( \cite{11} \) who also observed this dependence in Monte Carlo simulations. In the opposite case, \( V_0 = 5 \), we find that \( T_{SR}^{V_0=5} = 8 \pm 1 \), considerably higher than the \( V_0 = 1 \) temperature. This disagrees with the RG predictions of a universal \( T_{SR} \) independent of \( V_0 \). We believe that the agreement between our results and the previous ones \( \cite{10, 11, 12} \) indeed supports a dependence of \( T_{SR} \) on \( V_0 \), whose explanation remains an open question as far as RG is concerned.

A second, novel finding arises when considering our numerical results for \( V_0 = 5 \), which strongly suggest the possibility of two different low temperature phases. In our comments in the preceding paragraph, we took \( T_{SR}^{V_0=5} = 8 \pm 1 \) interpreting that the superroughening transition implies a change from a \( \ln^2 \) behavior of the height difference correlation function to a \( \ln \) form (and the rest of EW features). However, the lack of size dependence of the roughness and the specific heat on temperature below \( T^* = 5 \pm 1 \), with peaks absent for smaller values of \( V_0 \), raises the possible existence of another phase transition. If one looks at the correlation functions in Fig. \( 12 \) it turns out that for temperatures below \( T^* = 4 \) the correlation length is finite, in agreement with the roughness independence on the system size. Whereas the range of correlations above \( T^* \), which we believe is infinite, could be a subject of debate as we only have studied sizes up to \( L = 256 \), our claim of finite correlation lengths below \( T^* \) is difficult to dispute. Further evidence in this regard is shown in Fig. \( 12 \) where curves for \( V_0 = 5 \) at \( T = 1 \) are compared for two different system sizes. At this point, it is interesting to recall that in a previous paper \( \cite{17} \) it was found that at \( T = 0 \), the RsGM with \( V_0 = 1 \) exhibits a finite correlation length of about 20 lattice units (the reader may find Figs. 2 and 3 of \( \cite{17} \) illustrative). Having this in mind, it is not unreasonable to conjecture that there is a \( T^* \) for the \( V_0 = 1 \) case, which could be below \( T = 1 \) or close to \( T \) (the upper curve in Fig. \( 12 \) might already show a finite correlation length). We stress that this phase has not been previously reported in works at \( T = 0 \): Thus, Zeng et al. \( \cite{13} \) studied a discrete model but, being different from the Gaussian, their low temperature results can not be compared to ours, and the results of Rieger et al. \( \cite{15, 19} \) do not allow to conclude anything in this respect. Intuitively, one can expect a finite correlation length phase at low temperatures and large \( V_0 \); in the limit \( V_0 \to \infty \), the surface follows the disorder (i.e., \( h(r) = h(r)(0) + 2n(r)\pi \) everywhere), but the gradient term smoothens out the lack of correlations of \( h(0)(r) \), the competition of these two effects yielding a finite correlation length. In a loose sense, this could be interpreted as Anderson localization taking over the coupling between neighboring sites with increasing \( V_0 \). This picture is confirmed by simulations for \( V_0 = 25 \) (Fig. \( 12 \)): For such a large value of \( V_0 \) the correlation length is only 1 lattice unit, i.e., correlations reach only nearest neighbors. Clearly, the data presented here is not conclusive, but the conjecture that there are two transitions whose critical temperatures depend on \( V_0 \) is not unreasonable and deserves further consideration.

We have also found that the transition temperature and the correlation functions depend on the disorder strength. This is not unexpected, in so far as the change in the disorder distribution interacts with the periodicity of the sine potential, and therefore it is clear that when \( \epsilon = 2\pi \), i.e., in the standard RsGM, we are in a special case. In this respect, our results appear to indicate that the RsGM (with \( \epsilon = 2\pi \)) is a very specific model, and that its behavior at low temperatures might not be representative of what one would find in an actual experiment, where the disorder can not be so precisely controlled. Another conclusion we may draw from our work is that there might be two classes of behavior at low temperatures for small and large \( \epsilon \); Small \( \epsilon \) models would behave very similarly to the OsGM, whereas large values of \( \epsilon \) would give rise to a more complex phenomenology with, e.g., nonmonotonic behavior of the correlation functions.

As a final conclusion, we remark that the most relevant result of the present work is the determination of the transition temperature from the high temperature phase to the low temperature phase (or phases) of both the OsGM and the RsGM. This poses a number of questions...
to be addressed either with greater numerical capabilities or with new analytical tools. We believe that the complex phase diagram of the RsGM is being partially unveiled, as our research supports previous findings such as the non-universality of the transition temperature. Significantly, once we know where to look for the low temperature phase of the RsGM, we can investigate the nature of that phase (or phases). It is often stated that the RsGM is “glassy” in this regime; however, this assertion has never been really proven nor fully detailed and, furthermore, if the RG picture is qualitatively correct, it has to be recalled that it is a replica-symmetric theory, which implies that the superrough phase would not be glassy in the replica sense. We have obtained preliminary evidence that there are long-lived metastable states in the low temperature phase of the RsGM, but in view of our present results and their non-universality we will examine this question more carefully in future work. Investigation of the dynamics of the RsGM will also be important; we recall that Batrouni and Hwa did find evidence for a superroughening transition in the dynamics of the model, and hence it would be worth checking their results for larger values of $V_0$. We hope that those analyses, along with measurements of nonlinear susceptibilities and of relaxation dynamics, will shed light on this difficult problem. Work along these lines is in progress.

ACKNOWLEDGMENTS

We thank Rodolfo Cuerno, Juan Jesús Ruiz Lorenzo, and Raúl Toral for discussions. Work at Leganés was supported by project PB96-0119. Work at Los Alamos was done under the auspices of the U.S. Department of Energy. A.S. and E.M. acknowledge the support by NATO CRG 971090, by DGESIC (Spain) through a “Acción Integrada Hispano-Británica,” and by Los Alamos National Laboratory for a stay at Los Alamos, where part of this work was carried out.

FIG. 1: Mean energy for the OsGM and the RsGM vs temperature. Symbols as indicated in the plot. The straight lines correspond to the low temperature prediction (lower line) and the high temperature prediction (upper line). Inset: Specific heat vs temperature; symbols as in the main plot. Error bars are smaller than the symbol size.

FIG. 2: Total roughness for the OsGM and the RsGM vs temperature. Symbols as indicated in the plot. The straight lines correspond to the high temperature prediction for the two sizes considered. Inset: Roughness susceptibility vs temperature; symbols as in the main plot. Examples for error bars in different regions are shown.
FIG. 3: Height difference correlation functions (scaled by $T$) vs $\ln r$, $r$ being distance, for the OsGM (upper panel) and disordered (lower panel) sine-Gordon model. Temperatures are indicated at the right side of the plots. The curve marked with temperature 16 in the plot for the RsGM is the correlation function for the OsGM at that temperature, showing clearly that both overlap.

FIG. 4: Slope correlation functions (scaled by $T$) vs $\ln r$, $r$ being the distance, for the OsGM (upper panel) and disordered (lower panel) sine-Gordon model. Temperatures are indicated at the right side of the plots. The curve marked with temperature 16 in the plot for the RsGM is the correlation function for the OsGM at that temperature, showing clearly that both overlap.
FIG. 5: Comparison of the averages of the cosine term, $m_1$, of the OsGM and the RsGM at different temperatures. Symbols and lines as indicated in the plot; lines correspond to theoretical approximations up to order $\beta$ and $\beta^3$, whereas symbols are numerical results. Results are independent of the system size and of the realization of the disorder; error bars for thermal averages are smaller than the symbol size. The inset is an enlargement of the low $m_1$ region of the plot.

FIG. 6: Comparison of the roughness (upper panel) and specific heat (lower panel) for the OsGM and the RsGM for different values of $V_0$. The inset in the upper panel shows a larger range of temperatures for the roughness dependence. Symbols as indicated in the plot. All the results have been obtained for $L = 64$. Note especially the peak in the specific heat for the RsGM with $V_0 = 5$. 
FIG. 7: Comparison of the height difference correlation functions for the RsGM with $V_0$, $V_0 = 0.2$ (upper panel) and $V_0 = 5$ (lower panel). Temperatures as indicated in the plots.

FIG. 8: Comparison of the averages of the cosine term, $m_1$, of the OsGM and the RsGM for different values of $V_0$. Symbols as indicated in the plot, and lines correspond to the theoretical approximations for high temperature.
FIG. 9: Comparison of the roughness OsGM and the RsGM for $V_0 = 1, 5$ and sizes $L = 64, 128$. Symbols as indicated in the plot.

FIG. 10: Comparison of the roughness for the OsGM, the RsGM, and the two intermediate versions of the RsGM with disorder strength $\epsilon = 0.2$ and $\epsilon = 0.8$ (see text for the corresponding definition). The size is $L = 64$ in all four cases, and symbols are as indicated in the plot.
FIG. 11: Height difference correlation functions (scaled by $T$) vs $\ln r$, $r$ being distance, for the $\epsilon = 0.2$ (upper panel) and $\epsilon = 0.8$ (lower panel) RsGM. Temperatures are indicated at the right side of the plots. The curve marked with temperature 16 in the plot for the RsGM is the correlation function for the OsGM at that temperature, showing clearly that both overlap.

FIG. 12: Height difference correlation functions (scaled by $T$) vs $\ln r$, $r$ being distance, for different values of $V_0$ and $L$, as indicated in the plot. In all cases, $T = 1$.
