How to measure the Pomeron phase in
diffractive dipion photoproduction

Abstract

The study of charge asymmetry of pions in the high-energy process \( ep \rightarrow e\pi^+\pi^-p \)
\((\gamma p \rightarrow \pi^+\pi^-p)\) at very small dipion momenta offers a method to measure the phase of
the forward hadronic (quasi)elastic amplitude \( \gamma p \rightarrow pp \). We estimate potential of such
measurements at HERA.

1 Introduction

The phase \( \delta_F \) of the forward amplitude of the hadronic elastic scattering

\[
\mathcal{A} = |A|e^{i\delta_F} \equiv |A| \exp \left[ \frac{i\pi}{2} (1 + \Delta_F) \right]
\]

at high energy, treated often as a Pomeron phase, is an important object in hadron physics.

However, the object, studied in modern experiments and dubbed the Pomeron, seems
to be complex. In some models it is the same for all processes, in other models it
is process-dependent, which manifests itself in different effective intercepts in different
processes. The measurement of the phase of this object in various processes will be
a useful step towards clarification of its nature. For example, in the naive Regge-pole
Pomeron model, this phase is related directly to the Pomeron intercept, \( \Delta_F = -(\alpha_{IP} - 1) \),
in the model of a dipole Pomeron, \( \Delta_F = -(\alpha_{IP} - 1) - \pi/(2\ln(s/s_0)) \), [2], for the model
with Regge pole and cuts one adds to the value given by Pomeron pole intercept the
contribution of the branch cut with process dependent coefficient.

Up to the moment, a phase of such type was measured at very high energy only for
\( pp, \bar{p}p \) elastic scattering (via the study of Coulomb interference near forward direction,
see latest results [1] and references to earlier experiments therein). Such experiments de-
demand detailed measurement of the cross section at extremely low transverse momentum
of recorded particle, \( p_\perp \approx \sqrt{|t|} \lesssim 30 \text{ MeV} \), which translates into very small scattering
angles.

Here we propose to measure a similar phase for the process $\gamma p \rightarrow \rho p$ via the study of charge asymmetry of pions in the diffractive process

$$ep \rightarrow e\pi^+\pi^-p \quad (\gamma p \rightarrow \pi^+\pi^-p).$$

To describe our proposal in more detail, we denote by $p^\pm$ the momenta of the $\pi^\pm$ and

$$r^\mu = p^\mu_+ - p^\mu_-, \quad k^\mu = p^\mu_+ + p^\mu_-, \quad M = \sqrt{k^2}.$$  

We propose to measure charge asymmetry of pions in reaction (2) in the region

$$(20 \div 30) \text{ MeV} < k_\perp < 100 \text{ MeV}, \quad 1.1 < M < 1.4 \text{ GeV}.$$  

Essential part of our description is valid also at $M < 1.1 \text{ GeV}$. However, we do not present here definite predictions for experiment for this mass region due to complex structure of the $C$-even amplitude of dipion production here. At $M > 1.4 \text{ GeV}$ diffractive exclusive production of pion pairs becomes a too rare process to use it in the considered problems.

The main mechanism of the reaction in this domain is diffractive photoproduction of dipions in the $C$-odd state (the $\rho$-meson and its "tails", including $\rho'$) via the "physical Pomeron" — the vacuum quantum number exchange in $t$-channel. The phase of the amplitude of this "physical Pomeron" (1) is the main subject of our study. Besides, dipions can be produced in the $C$-even state via (i) the $\rho$, $\omega$ Regge exchange, (ii) the odderon exchange and (iii) the one-photon exchange with proton (the Primakoff effect).

The interference of amplitudes of the $C$-odd and $C$-even dipion production provides charge asymmetry of the observed pion distribution. The experimental study of this charge asymmetry is a good tool for the investigation of a number of phenomena [4].

These exchanges have very different dependence on the transverse momentum of dipion $k_\perp$.

The Primakoff effect is strongly peaked at small transverse momenta of dipion $k_\perp$. It can be neglected at $k_\perp > 200 \text{ MeV}$ (see details in the text below). It is natural to expect that the odderon contribution, just as the $\rho/\omega$ Reggeon exchanges, has a flatter $k_\perp$ dependence, similarly to other hadronic amplitudes. Besides, the contribution of the $\rho/\omega$ Reggeon exchanges was estimated as very small in the HERA energy region [5], and according to modern data the odderon contribution is low enough, so that both these contributions can be neglected at the considered low transverse momenta (4). Therefore, (see [6])

(i) At $k_\perp < 100 \text{ MeV}$ the charge asymmetry discussed is described by an interference of the Pomeron contribution with the Primakoff one, and it is sensitive to the phase $\delta_F$. This sensitivity offers a method to measure $\delta_F$ in the discussed experiments.

(ii) At $k_\perp \approx 0.3–1 \text{ GeV}$ the Primakoff contribution is negligible, the discussed charge asymmetry is described by an interference of the Pomeron and odderon contributions, and this very experiment provides an opportunity to discover the odderon [5], [6].

Proposed experimental set-up. We suggest to observe dipion final state without other particles in detectors (without observation of scattered proton or electron). The pions that hit the detector have transverse momenta $p_{\perp} \sim M/2 \sim 500 \text{ MeV}$ with emission angles $20 \div 150 \text{ mrad}$, which looks not so difficult to measure. It is the sum of the transverse momenta of the two pions $k_\perp$ that is supposed to be small and measurable. So, in order for this method to be efficient, we need a reasonable resolution of the reconstruction of each pion’s transverse momentum. The choice of the lower bound in $k_\perp$ (4) corresponds to the anticipated accuracy of this measurement.
Let us stress a vital feature of our suggestion. The procedure we propose does not
demand the measurement of very small scattering angles of pions.

The quality of this set-up can be controlled via measurement of charge symmetric
part of cross section (CSP) by two ways. First, the observation of events with the
same pion content and recording of scattered electron with \( k_{\perp e} \leq 30 \div 50 \text{ MeV} \) has
low efficiency. However these observations will give CSP in the considered kinematical
region with good enough accuracy. Second, the known results for the CSP at higher total
transverse momentum (obtained with recording of electron and proton) can be used for
extrapolation in the kinematical region under interest.

- In the next section we discuss kinematics of the process and introduce the charge
asymmetric variables. In Section 3 we present well known amplitudes of
\( C \)–odd and
\( C \)–even dipion production. In Section 4 we study the differential cross section and find
the integral charge asymmetries. In Section 5 we present numerical results for \( \gamma p \) and
\( ep \) collisions. Discussion and conclusions are found in Section 6.

2 Kinematics

In the proposed set-up without recording of electrons, the main contribution to the
\( ep \rightarrow e\pi^+\pi^- p \) cross section is given by convolution of equivalent photon spectrum with
cross section of mass shell \( \gamma p \rightarrow \pi^+\pi^- p \) subprocess. In the considered region of \( k_{\perp} \)
accuracy of this equivalent photon (or Weiszacker–Williams) approximation is very high
(much better than \( k_{\perp max}^2/m_p^2 \)). We stress again that the procedure we propose does not
demand the measurement of very small scattering angles of pions. Therefore we focus
first on the subprocess – the dipion quasielastic photoproduction off proton \( \gamma p \rightarrow \pi^+\pi^- p \)
considering the limitation in \( k_{\perp} \) (4) as that for this subprocess. The convolution with
equivalent photon spectrum is considered in sec. 4.2.

Process \( \gamma p \rightarrow \pi^+\pi^- p \). The energies we have in mind correspond to the HERA
energy range \( (\sqrt{s_{\gamma p}} \sim 100 \div 200 \text{ GeV}) \). The initial momenta of the photon and proton
are \( q \) and \( P \) respectively, \( s = (q + P)^2 \), initial photon polarization vector is \( \vec{e} \). We use
kinematical variables (3) for this process as well.

We define the \( z \)-axis as the \( \gamma p \) collision axis and label the vectors orthogonal to this
axis by \( \perp \). Let us denote by \( z_+ \) and \( z_- \) the standard light cone variables for each charged
pion, \( z_+ \approx \frac{(e_+ + p_+)}{2E_+} = \frac{(p_+P)}{2(E \gamma)} \) (for the considered process \( z_+ + z_- = 1 \)).

We direct the \( x \)-axis along vector \( \vec{k}_{\perp} \) and define by \( \psi \) the azimuthal angle of the
linear photon polarization with respect to the fixed lab frame of reference. For instance,
for the photon in electroproduction \( ep \rightarrow e\pi^+\pi^- p \) virtual photons are polarized in the
electron scattering plane and \( \psi \) is the azimuthal angle relative to the electron scattering
plane. Then the polarization vector of the initial photon with helicity \( \lambda_\gamma = \pm 1 \) can be
written as \( \vec{e}_\lambda = -\frac{1}{\sqrt{2}} e^{-i\lambda \gamma \psi}(\lambda_\gamma, i) \).

It is useful also to consider polar and azimuthal angles of \( \pi^+ \) in the dipion c.m.s., \( \theta \)
and \( \phi \), and the velocity of a pion in this frame \( \beta = \sqrt{1 - 4m^2/\gamma M^2} \), so that \( r_{c.m.s.} =
\beta M(0, \sin \theta \cos \phi, \sin \theta \cos \phi, \cos \theta) \). We denote by \( J \) the total angular momentum
(totall spin) of dipion, by \( \lambda_\gamma \) and \( \lambda_{\pi^+\pi^-} \) – the helicities of photon and produced dipion,
respectively, and by \( n = |\lambda_\gamma - \lambda_{\pi^+\pi^-}| \) – the value of helicity flip for each amplitude. (The
final results are averaged over initial photon polarizations.) Instead of phase analysis in
terms of these angular variables, many physical problems can be solved definitely via the
measurement of charge asymmetry of pions.

The phenomenon of charge asymmetry is the difference in distributions of particles
and antiparticles. It is determined by the part of differential cross section that changes its sign under $\tau^\mu \rightarrow -\tau^\mu$ change. Particularly, we describe the forward–backward (FB) and transverse (T) asymmetries by variables

\[ FB : \xi = \frac{z_+ - z_-}{\beta(z_+ + z_-)} = \cos \theta, \]
\[ T : v = \frac{p^2_{\perp} - p^2_{\perp} - \xi k^2_{\perp}}{\beta M |k_{\perp}|} = \frac{(\rho_{\perp} k_{\perp})}{\beta M |k_{\perp}|} = \sin \theta \cos \phi; \quad \rho_{\perp} = r_{\perp} - \xi k_{\perp}. \] (5)

We consider the amplitude of the dipion production $A$, which is normalized so that

\[ d\sigma = |A|^2 \beta dM^2 d\xi dv \frac{d\psi}{2\pi} = \frac{2}{\sqrt{1 - \xi^2 - v^2}} |A|^2 \beta dM^2 dk_{\perp}^2 d\xi dv \frac{d\psi}{2\pi}. \] (6)

We will see below that only transverse asymmetry arises in the considered case. We describe the values of this charge asymmetry and the charge symmetric background by quantities

\[ \Delta \sigma_T = \int d\sigma(v > 0) - \int d\sigma(v < 0), \quad \sigma_{bgd} = \int d\sigma, \] (7)

with integration over (identical) suitable region of final phase space.

3 The amplitudes

Note first that in the considered range of momentum transfer (4) the inelastic transitions in the proton vertex as well as helicity-flip elastic transitions are small.

• The C-odd dipion diffractive production is described by the "physical Pomeron". It has been studied both in theory and in experiment (e.g. at HERA) as a production of C–odd resonances, mainly $\rho(770)$ meson with well known properties.

Our basic assumption is that the amplitude can be written in a form

\[ A = \sum_{Jn} A_{Jn}(s, t, M^2) D_J(M^2) \epsilon^{\lambda_\gamma, \lambda_{\pi\pi}}. \] (8)

(i) The first factor $A_{Jn}(s, t, M^2)$ is "the Pomeron amplitude" for the production of the dipion state with effective mass $M$, angular momentum $J$ and helicity flip $n$. In the considered mass region the contribution with $J = 1$ dominates (the admixture of $J = 3$ looks negligible). In discussions we assume that in the considered mass interval the entire dependence of amplitude $A$ on dipion mass $M$ at $t \approx 0$ can be accumulated with high precision in the factor $D_J(M^2)$ so that the amplitude $A_{Jn}$ is only weakly dependent on the dipion mass $M$. It is normalized in the $\rho$–meson peak in such a manner that $A_{Jn=0}(M = M_{\rho}) = e^{i\delta_F}|A_{Jn}|$ with

\[ |A_{Jn}|^2 = \sigma_{\rho} B e^{-B k_{\perp}^2} \] (9)

with $B \approx 10$ GeV$^{-2}$, $\sigma_{\rho} \approx 11 \mu$b.

The $s$-channel helicity conservation $\lambda_{\pi^+\pi^-} = \lambda_\gamma$ for process (2) is a well established fact. For the considered $k_{\perp}$ region, the helicity violating amplitudes are as small as $\sim (|k_{\perp}|/M)^n \leq (0.03)^n$, and we neglect them below. Last, in the considered region (4) the $t$–dependence of the amplitude is negligible.

(ii) The second factor $D_J(M)$ describes the decay of this dipion state to pions — it is driven by strong interaction of pions in the final state. In similarity to construction
of the pion formfactor, It should be constructed from contributions of $\rho, \rho’, \rho''$ in a manner to describe data in the effective mass interval considered. At $2m_\pi < M < M_\rho$ one can use for $D_1$ the well known Gounaris–Sakurai approximation obtained for the pion form-factor. At $M > M_\rho$ one should take into account also $\rho’, \rho’’$ states with variable parameters given by coupling constants and parameters of $\rho’, \rho’’$. The reasonable parameterization should give complete description of dipion mass spectrum $\propto |D_1|^2$ in the considered region\(^1\). Below, we use the fit from [7]. It covers the required mass interval and includes $\rho$ running width and $\rho’/\rho’’$ states. Note that the parameters of the model can be fixed with a better accuracy with detailed measurement of the dominant $C$–even dipion mass spectrum in the very experiment we propose.

The qualitative discussion becomes transparent with the standard Breit–Wigner factor for $R = \rho(770)$ (including $R\pi^+\pi^-$ coupling)

$$D_J(M^2) \approx \frac{\sqrt{m_R \Gamma_R} \Gamma(R \rightarrow \pi^+\pi^-) / \pi}{-M^2 + m_R^2 - i m_R \Gamma_R}.$$  \hspace{1cm} (10)

(iii) The third factor $E_J^{\lambda_\gamma, \lambda_{\pi\pi}}$ describes the angular distribution of pions in their rest frame. $E_J^{\lambda_\gamma, \lambda_{\pi\pi}} = Y_J^{\lambda_\gamma, \lambda_{\pi\pi}}(\theta, \phi) e^{-i \lambda_\gamma \psi}.$

Finally, the amplitude of the $C$–odd dipion photoproduction reads as

$$A\gamma = e^{i \delta_\gamma} \cdot |A_{1,0}(s)| \cdot D_1(M^2) \cdot \sqrt{3/8\pi} \sin \theta e^{i \lambda_\gamma (\phi - \psi)}$$
$$\equiv e^{i \delta_\gamma} \cdot |A_{1,0}(s)| \cdot D_1(M^2) \cdot \sqrt{3/8\pi} \sqrt{1 - \xi^2} e^{i \lambda_\gamma (\phi - \psi)}.$$  \hspace{1cm} (11)

Here and below subscript $–$ or $+$ at $A$ denotes the $C$–parity of the produced dipion.

• **The amplitude of the production of $C$–even dipions via Primakoff effect** is the same as that in the two–photon processes $e^+ e^- \rightarrow e^+ e^- \pi^+\pi^-$ \cite{10, 11}. In the regions under interest (4) the dominant contribution is given by the almost real photon exchanges with both electron and proton. Therefore, the total helicity of the initial two–photon state and respectively of dipions can be 0 and 2. The amplitude can be written in a form similar to eq. (8).

Beginning from the threshold, the pions interact strongly in the $I = J = 0$ state (which is described by $f_0$ resonances). The other partial waves are described well with the QED approximation for point–like pions (with known small modifications). The QED amplitude with $I = 0, J = 2$ become surprisingly large starting from $M = 0.5 – 0.7$ GeV. The other amplitudes can be neglected everywhere in our problem.

At $M^2 \ll \sigma_\gamma$ the amplitude of the Primakoff $\gamma \gamma \rightarrow R\pi$ process can be written \cite{10} via the two-photon decay width $\Gamma_{\gamma\gamma}$ of the resonance $R$ with spin $J$

$$A_\gamma = \sqrt{\sigma_2} \cdot \frac{|k|}{k^2 + Q^2_m} \text{ with } Q^2_m = \left( \frac{m_p M^2}{s} \right)^2, \quad \sigma_2 \equiv \frac{8 \pi \alpha \Gamma_{\gamma\gamma} (2J+1)}{m_R^2}.$$  \hspace{1cm} (12a)

Here, $Q^2_m$ is the minimal value of the virtuality of the exchanged photon (typically $Q^2_m < m_e^2$).

\(^1\) To take into account possible dependence $B(M)$, one should distinguish here a quantity defined at $t = 0$ and that obtained by extrapolation procedure, the second quantity can contain also factor appearing due to $t$–integration of $e^{-B_M k^2}$. These quantities will be obtained from two different methods of verification of the proposed set-up (see end of sec. 1). The first method gives the quantity at $t \approx 0$, the second method CAN include integration over $t$. 

5
At 1.1 < M < 1.4 GeV, the main contribution is given by the I = 0, J = 2 partial wave, other partial waves being negligible. Here $f_2(1270)$–meson (J = 2) production dominates. We define by $g_0$ and $g_2$ the relative probability amplitudes of the dipion production in the states with helicity 0 and 2; $g_0^2 + g_2^2 = 1$. According to data, the contribution of total helicity $\lambda_{\pi\pi} = 2$ dominates, i.e. $g_2 \gg |g_0|$ (see e.g. [9]). Similarly to (11), the amplitude of the process can be written as

$$A_+ = A_γ \cdot D_2(M^2) \cdot (g_2 Y_{2,2}(θ, φ) + g_0 Y_{2,0}(θ, φ)) e^{-iλγψ},$$

$$\equiv A_γ \cdot D_2(M^2) \cdot \sqrt{\frac{15}{32π}} \left[ g_2(1 − ξ^2)e^{2iλγψ} + g_0 \sqrt{\frac{2}{3}}(3ξ^2 − 1) \right] e^{-iλγψ}. \quad (12b)$$

with $D_2$ factor given by eq. (10) with $R = f_2(1270)$.

For more precise calculation the QED contribution should be also accounted for. In the unitarized model describing the data near the $f_2$ peak constructed in [8] the $I = 0, J = 2$ partial wave contains a phase-shifted Breit-Wigner factor and a modified Born QED term:

$$D_2(M^2) = \frac{\sqrt{m_fΓ_f(M^2)Br(f_2 → π^+π^-)/π}}{-M^2 + m_f^2 − im_fΓ_f(M^2)} \cdot e^{iκ} + D_2^{QED}(M^2). \quad (13)$$

The mass dependence of the $f_2$ width $Γ_f(M^2)$ and the parametrization for the modified QED contribution $D_2^{QED}(M^2)$ were taken from [8]. The phase factor $e^{iκ}$ represents one particular possibility to effectively fulfil the unitarity constraint: the value of $κ$ is such that $D_2$ becomes purely imaginary at $M = m_f$.

### 4 Cross sections

#### 4.1 Differential cross section. Photoproduction.

The differential cross section of the $γp → π^+π^-p$ sub-process at 1.1 < M < 1.4 GeV averaged over the initial photon polarizations is

$$dσ = 2 \frac{|A_− + A_+|^2}{\sqrt{1 − ξ^2 − v^2}} β dM^2dk^2_⊥dξdv = dσ_{sym} + dσ_{asym}, \quad (14)$$

$$\frac{dσ_{sym}}{dM^2dk^2_⊥dξdv} = \frac{2β}{\sqrt{1 − ξ^2 − v^2}} \left\{ |A_{1,0}(s)|^2 |D_1(M^2)|^2 \frac{3}{8π}(1 − ξ^2) + \frac{15}{16π} A_γ^2 |D_2|^2 \left[ \frac{g_2^2}{2}(1 − ξ^2)^2 + 3g_0^2(ξ^2 − \frac{1}{3})^2 + g_0g_2\sqrt{6}(ξ^2 − \frac{1}{3})(2v^2 + ξ^2 − 1) \right] \right\}, \quad (15)$$

$$\frac{dσ_{asym}}{dM^2dk^2_⊥dξdv} = v \cdot \frac{β}{\sqrt{1 − ξ^2 − v^2}} \cdot \frac{3\sqrt{5}}{4π} |A_{1,0}(s)| A_γ \cdot Re \left[ D_1e^{iδ_F}D_2^⊥ \right] \cdot \left[ g_2(1 − ξ^2) + g_0\sqrt{\frac{2}{3}}(3ξ^2 − 1) \right]. \quad (16)$$

Here $dσ_{sym}$ represents the charge-symmetric contribution, which comes from the squares of the Pomeron and of the Primakoff amplitudes. The interference between these amplitudes produces the charge asymmetric contribution $dσ_{asym}$. Since the phase
\(\delta_F\) enters only \(d\sigma_{\text{sym}}\), we need to extract charge asymmetry, for this task the charge symmetric contribution \(d\sigma_{\text{sym}}\) is a background.

The appearance of factor \(v\), describing transverse charge asymmetry, in the interference term is very natural. First, due to integration over \(\psi\), we are left with terms diagonal in photon polarization states, i.e. \(\lambda_\gamma\) is the same in \(A_\pm\) and in \(A^+\). Then, \(A_-A^+_\parallel\) can be rewritten as a charge symmetric factor multiplied by \(\sin \theta e^{\pm i \lambda_\gamma \phi}\). The averaging over initial photon polarizations means that we sum contributions with opposite helicities, i.e. consider the sum which is proportional to \(\sin \theta e^{\pm i \lambda_\gamma \phi} + h.c. \Rightarrow v\).

In other words, the averaging over photon polarization transforms complex factors from the spherical harmonics to the real factor describing charge asymmetry.

For our case when one can consider only one partial wave in the Primakoff amplitude, the \(M\) dependence in \(d\sigma_{\text{sym}}\) is described completely by the overlap function, which is independent on the \(g_0\) and \(g_2\) interrelation,

\[
I_{\rho f}(M^2) = Re \left[ D_1 e^{i \delta_F} D^*_2 \right].
\] (18)

The shape of \(M\)-dependence. Fig. 1 demonstrates the overlap functions for several Pomeron models. The parameterization for \(D_1\) was taken from [7] (with \(\rho/\rho' / \rho''\) parameters and running of the \(\rho\) width taken into account), while the parametrization for \(D_2\), which included both the \(f_2\) resonance and the \(I = 0, J = 2\) modified born term, was taken from [8]. The four black curves correspond here to different Pomeron models. The solid, dashed, and dotted curves correspond to the simple pole Pomeron model with \(\Delta_F = 0, 0.08,\) and 0.16, respectively. The dashed-dotted curve represents one particular parametrization of a dipole Pomeron model, [2], calculated for \(\sqrt{s_{\gamma p}} = 50\) GeV. In each of the four cases, the grey region corresponds to 1\(\sigma\) variations of the parameters in \(D_1\) used. The resulting shaded region allows one to see the typical level of inaccuracy that arises from the parameterizations used. It is not large, and allows one to discern different Pomeron models for \(M_{\pi\pi}\) interval below the \(f_2\) peak.

Note that many qualitative features can be easily understood in the simplified \(\rho\)-meson model for \(D_1\) (10). It was found numerically that this approximation gives also reasonable quantitative approximation for the overlap function.

Dependence on the momentum transfer. Integrating the differential cross section (7) over the whole \(\xi, v\) space, within mentioned \(M\) interval, and with \(k_\perp\) interval \(k_{\text{max}} > k_\perp > k_{\text{min}}\) (4), one obtains:

\[
\sigma_{\text{bkgd}} = \sigma_B C_1 (k_{\text{max}}^2 - k_{\text{min}}^2) + \sigma_2 C_2 \ln \frac{k_{\text{max}}^2}{k_{\text{min}}^2 + Q_m^2}, \quad C_i = \int dM^2 |D_i(M^2)|^2 - \Delta \sigma_{\text{bkgd}} - \Delta \sigma_{\text{sym}},
\] (19)

Numerical estimates show that the second term here, which represents the Primakoff contribution, can be neglected at considered values \(k_{\text{max}}\) and \(k_{\text{min}}\) (4). The integral value of the charge asymmetry, \(\Delta \sigma_{\text{chas}, T}\), calculated in the same \(M\) and \(k_\perp\) regions, is

\[
\Delta \sigma_{\text{chas}, T} = \frac{9 \sqrt{3}}{8} \sqrt{\sigma_B} \cdot \sigma_2 \cdot \Delta I_{\rho f} \cdot (k_{\text{max}} - k_{\text{min}}), \quad \Delta I_{\rho f} = \int dM^2 I_{\rho f}(M^2).
\] (20)

To obtain simple estimates, we set \(g_2 = 1, g_0 = 0\).

4.2 \(ep\) collisions

We think that the most efficient way to study the problem under interest is to investigate dipion production in \(ep \to e\pi^+\pi^- p\), e.g. at HERA without recording of scattered electron and proton (and without other particles in detector except \(\pi^+\) and \(\pi^-\)).

7
Figure 1: Overlap function $I_{\rho \kappa}$ vs. $M^2$. The black solid, dashed, and dotted curves correspond to simple pole Pomeron model with $\Delta_F = 0$, 0.08, and 0.16, respectively. The dashed-dotted curve represents one particular parametrization of a dipole Pomeron model, [2], calculated for $\sqrt{s_{\gamma p}} = 50 \text{ GeV}$. In each of the four cases, the grey region corresponds to $1\sigma$ variations in the parameters of $\rho'$, $\rho''$ and $f_2$ resonances.

The $ep$ cross section is given by a convolution of the virtual photon flux originating from the electron with the cross section of the $\gamma p$ subprocess. The dominant part of the $ep$ cross section comes from region of very small virtuality of the emitted photon. That is the base of the equivalent photon approximation (see e.g. [10]), in which the flux of the equivalent photons with energy $\omega = y E_e$ and transverse momentum $q_\perp$ is

$$dn_\gamma = \frac{\alpha}{\pi} \frac{dy}{y} \left[ 1 - y + \frac{y^2}{2} - (1 - y) \frac{q^2}{q^2_{\perp}} \right] \frac{\frac{q^2}{q^2_\perp} dq^2_{\perp}}{(q^2_\perp + q_e^2)^2} \text{ with } q^2_e = \frac{m^2 y^2}{1 - y}. \quad (21)$$

Note that the photon energy $\omega$ coincides with the total dipion energy with high accuracy.

The main contribution to the $ep$ cross section originates from the region of virtualities $q^2_\perp/(1 - y) + q_e^2$ much lower than the characteristic scale of hadronic interactions. Therefore, (i) the distribution is peaked at very small $q_\perp$ when the scattered electron escapes observation, (ii) with high enough accuracy one can take for the amplitudes of
\(\gamma p\) subprocess their on-shell values discussed above, \((iii)\) the precision of eq. (21) is very high (much better than \(k_{\text{max}}^2/m_p^2\)). At this transition from photons to electrons, the quantities (5) that describe the charge asymmetry are transformed as follows: the FB variable \(\xi\) stays unchanged since it is independent of small change of transverse momentum and keeps its form under the longitudinal boost; the transverse variable \(v\) will be now defined by the same expression (5), but in terms of the transverse dipion momentum \(K^*_\perp = q_\perp + k_\perp\) with respect to \(ep\) collision axis.

The differential cross section of dipion production in \(ep\) collisions is given by convolution of flux (21) with (14), (17). For numerical estimates in our kinematical region (1) it is useful to change the \(k_\perp^2\) dependence from (9) to \(1/(1 + Bk_\perp^2)\) which is good approximation at considered \(Bk_\perp^2 < 0.1\). In the region (4) we have also \(K_\perp^2 \gg Q_m^2, q_e^2\) and the charge symmetric part of cross section can be written as (see e.g. [10])

\[
\frac{d\sigma_{\text{sym}}^{ep}}{dM^2 dK_\perp^2 d\xi dv dy} = \frac{\beta}{\sqrt{1 - \xi^2 - v^2}} |A_{1,0}(s)|^2 |D_1(M^2)|^2 \frac{3}{4\pi} (1 - \xi^2) \\
\cdot \frac{\alpha}{\pi y} \left[ \left( 1 - y + \frac{y^2}{2} \right) \cdot \left( \log \frac{1}{B q_e^2} - 1 \right) - (1 - y) \right],
\]

\[
\frac{d\sigma_{\text{asym}}^{ep}}{dM^2 dK_\perp^2 d\xi dv dy} = \frac{\beta}{\sqrt{1 - \xi^2 - v^2}} \sigma_2 |D_2(M^2)|^2 \\
\cdot \frac{15}{8\pi} \left[ \frac{q_e^2}{2} (1 - \xi^2)^2 + 3g_0^2 \left( \xi^2 - \frac{1}{3} \right)^2 + g_0 g_2 \sqrt{6} \left( \xi^2 - \frac{1}{3} \right) (2v^2 + \xi^2 - 1) \right] \\
\cdot \frac{\alpha}{\pi y (K_\perp^2 + Q_m^2 + q_e^2)} \left[ \left( 1 - y + \frac{y^2}{2} \right) \cdot \left( \log \frac{(K_\perp^2)^2}{Q_m^2 q_e^2} - 2 \right) - (1 - y) \right].
\]

Note that in the Primakoff contribution we also keep term \(Q_m^2 + q_e^2\) in the denominator, which is negligible in the considered kinematical range but useful in the estimate of total cross section.

The charge asymmetric contribution is written now via new value \(v\) as

\[
\frac{d\sigma_{\text{asym}}^{ep}}{dM^2 dK_\perp^2 d\xi dv dy} = \frac{\beta \cdot \alpha |K_\perp|}{\pi y K_\perp^2} \left[ \left( 1 - y + \frac{y^2}{2} \right) \cdot \left( \log \frac{K_\perp^2}{q_e^2} - 1 \right) - \frac{1 - y}{2} \right] \cdot \mathcal{I}_{\rho f}(M^2).
\]

The total values of the signal and background integrated over entire region (4) similar to those written in eq-s (19), (20) and with the same notations, written with logarithmic accuracy (for estimates), are

\[
\frac{\sigma_{\text{bkgd}}^{ep}}{dy} = N_\gamma(y) \left[ \sigma_p B C_1 \ln \frac{1}{B q_e^2} (K_{\text{max}}^2 - K_{\text{min}}^2) + \sigma_2 C_2 \ln \frac{K_{\text{max}}^2}{K_{\text{min}}^2} \ln \frac{K_{\text{max}}^2 K_{\text{min}}^2}{Q_m^2 q_e^2} \right],
\]

\[
\frac{\Delta\sigma_{\text{chas},T}^{ep}}{dy} = N_\gamma(y) \frac{9\sqrt{5}}{8} \sqrt{\sigma_p B \cdot \sigma_2} \cdot \Delta\mathcal{I}_{\rho f} \cdot \left( K_{\text{max}} \ln \frac{K_{\text{max}}^2}{q_e^2} - K_{\text{min}} \ln \frac{K_{\text{min}}^2}{q_e^2} \right).
\]

Here \(N_\gamma(y) = (\alpha/\pi y)(1 - y + y^2/2)\).
5 Estimates of the effect

5.1 Extracting charge asymmetry

For the integrated luminosity \( \mathcal{L} \), the statistical significance of the result is given by the ratio of the number of events under interest \( \mathcal{L} \Delta \sigma_{chas,T} \) to the dispersion of background events \( \sqrt{\mathcal{L} \sigma_{bkgd}} \):

\[
SS = \frac{\mathcal{L} \Delta \sigma_{chas,T}}{\sqrt{\mathcal{L} \sigma_{bkgd}}}. \tag{24}
\]

In particular, we consider local statistical significance \( SS(M) \) defined by this very equation for fixed value of dipion mass \( M \), \( SS(M) = \mathcal{L} d \Delta \sigma_{chas,T} / d M^2 / \sqrt{\mathcal{L} d \sigma_{bkgd} / d M^2} \). The study of shape of this \( SS(M) \) helps us in the choice of cuts in \( M \) for data processing.

Fig. 2 shows this local statistical significance. For the \( C \)-odd dipions, as said above, we assume the \( \rho \)-meson dominance with \( |A_{1,0}| \) given by eq. (9). For \( f_2 \) meson production, \( \sigma_2 \) in (12a) is \( \sigma_2 = 0.42 \) nb. Besides, we set \( g_0 = 0 \), \( g_2 = 1 \) in accordance with data for \( f_2 \) production in photon collisions. All other parameters were already discussed.

Let us remind that the diffractive dipion photo-production dominates over Primakoff
contribution in the C–even part of cross section. Therefore, in the mass region, where \( f_2 \) production dominates in Primakoff effect, the local statistical significance is estimated as

\[ SS(M) \propto \text{Re}(D_2^* e^{i\delta F} D_1)/|D_1| \leq |D_2(M)| \]

This suggests that the largest statistical significance comes approximately from the region under the \( f_2 \) meson peak \( m_f - \Gamma_f < M < m_f + \Gamma_f \). This is the reason why we study here the charge asymmetry only in the region \( 1.1 < M < 1.4 \text{ GeV} \).

Integration of \( |D_i|^2 \) and of the overlap function \( I_{\rho f} \) over this range gives for quantities in (23) at \( \Delta F = 0 \)

\[ \Delta I_{\rho f} = \int dM^2 I(M^2) = 0.114; \quad C_1 = \int dM^2 |D_1(M^2)|^2 = 0.045; \quad C_2 = \int dM^2 |D_2(M^2)|^2 = 0.36. \]

Note that the value of \( \Delta I_{\rho f} \) depends on \( \Delta F \) only weakly.

5.2 Numerical estimates

- \( \gamma p \) collisions. Now the statistical significance of observation of charge asymmetry (24) is evidently independent of the upper cut \( k_{\text{max}} \). The upper cut \( k_{\text{max}} = 100 \text{ MeV} \) guarantees that the odderon contribution is negligible. The resulting cross sections are

\[ \sigma_{\text{bkgd}} = 49 \text{ nb}; \quad \Delta \sigma_{\text{chas},T} = 5.2 \text{ nb}; \quad SS_T \approx 24 \cdot \sqrt{L_{\gamma p}(\text{pb}^{-1})}. \]

- \( ep \) collisions. For the \( ep \) collisions, we take, for definiteness, \( L_{ep} = 100 \text{ pb}^{-1} \) and integrate over the \( y \)-interval \( 0.2 < y < 0.8 \). We then obtain the following values of the cross sections and of the statistical significance

\[ \sigma_{\text{bkgd}}^{ep} \approx 1.5 \text{ nb}, \quad \Delta \sigma_{\text{chas},T} \approx 0.13 \text{ nb} \Rightarrow SS_T \approx 34. \]

Sensitivity to \( \delta_F \). The above values of the integral \( SS \) show that the effect is observable at HERA with good confidence. We hope that after dedicated specification of the models for \( D_i \), a detailed study of the \( M \)-shape of this charge asymmetry will allow for extraction of the Pomeron phase \( \delta_F \) with reasonable precision.

6 Discussion and conclusions

We showed that the interference between the Pomeron exchange and the Primakoff effect contributions gives charge asymmetry in pion distributions. The absolute value and the shape of \( M \)-dependence of this charge asymmetry is sensitive to the phase of the strong amplitude (the Pomeron phase) \( \delta_F \). Accurate study of this shape can lead to a direct measurement of \( \delta_F \). Our estimates show that this effect can be studied at HERA.

The approach suggested avoids the problems associated with the measurement of very small transverse momenta of the detected particles, in contrast to the strong–Coulomb interference in elastic \( pp \) scattering (where one should measure transverse momenta \( p_\perp \lesssim 100 \text{ MeV} \)). Here, detected pions have typical transverse momenta \( |p_\perp| \sim 500 \text{ MeV} \) (for higher \( M \)), which looks measurable better than proton momenta in the mentioned case of Coulomb interference.

Equations written in the text allow one to obtain preliminary estimate for \( \delta_F \) and find its \( s \) dependence with accuracy limited by details of experimentation. A more precise
extraction of the absolute value of $\delta_F$ demands more accurate models both for Pomeron and Primakoff amplitudes. The main features of these models are well known, and these models can be further improved right in the course of dedicated experiments on charge asymmetries (both at high-energy lepton-hadron or low-energy $e^+e^-$ colliders). The sketch of how predictions can be made more precise is given in the text. The invariant mass interval $M = 1.1 \div 1.3$ GeV seems to be particularly suitable, since theoretical predictions can be made more precise here. For each mass interval, these problems should be studied separately.

- **The case $M < 1$ GeV.** At lower dipion invariant masses, $M \lesssim 1$ GeV, the study of the transverse charge asymmetry can also be used for extraction the Pomeron phase. A more detailed model for the $\gamma\gamma \rightarrow \pi^+\pi^-$ reaction is necessary to make more accurate predictions for the study of the Pomeron phase. This model can be verified by measurement of similar charge asymmetry in the process $e^+e^- \rightarrow e^+e^-\pi^+\pi^-$ at modern $e^+e^-$ colliders [11]. That is the subject of forthcoming studies.

  Preliminary estimates show that below the $\rho$ peak the phases of factors $D_1$ and $D_0$ are close to each other, so that the contribution of their interference term to the considered symmetry is small. The dominant contribution to the charge asymmetry is given here by the $\rho/QED$ interference. The best statistical significance of charge asymmetry comes from the region $M = 0.4 \div 0.8$ GeV.

- The extension of this idea to nuclear targets is straightforward. A detailed treatment of charge asymmetry in dipion production in $eA$ collisions (e-RHIC or nuclear LHC) will be given elsewhere.

We are thankful to A.B. Kaidalov, N.N. Nikolaev, D.Yu. Ivanov, V.V. Serebryakov, V.G. Serbo and G.N. Shostakov for valuable comments. IPI is also thankful to Prof. R. Fiore for hospitality at INFN, Cosenza, where the paper was finished. This work was supported by INTAS grants 00-00679 and 00-00366, RFBR grant, NSh-2339.2003.2.
