ABSTRACT
Most current anomaly detection methods suffer from the curse of dimensionality when dealing with high-dimensional data. We propose an anomaly detection algorithm that can scale to high-dimensional data using concepts from the theory of large deviations. The proposed Large Deviations Anomaly Detection (LAD) algorithm is shown to outperform state of art anomaly detection methods on a variety of large and high-dimensional benchmark data sets. Exploiting the ability of the algorithm to scale to high-dimensional data, we propose an online anomaly detection method to identify anomalies in a collection of multivariate time series. We demonstrate the applicability of the online algorithm in identifying counties in the United States with anomalous trends in terms of COVID-19 related cases and deaths. Several of the identified anomalous counties correlate with counties with documented poor response to the COVID pandemic.

Large deviations, anomaly detection, high-dimensional data, multivariate time series

1 INTRODUCTION
Anomaly detection has been extensively studied over many decades across many domains [9, 18]. Among the most useful applications of anomaly detection is to simultaneously monitor multiple systems’ behaviors and identify the system that exhibits anomalous behavior due to external or internal stress factors. For instance, consider the example of the COVID-19 infection data. Studying the confirmed case and death trends across various countries, states or counties could highlight and identify the most (or least) significant public policies. One possible approach to study the data could be to monitor each time series [8, 20, 30] and identify sudden outbreaks or significant causal events. However, such methods study each time series individually and cannot be used to detect the gradual divergence from the normal trends or initial signs of such drift.

An alternate approach is to analyze each time series in the context of a collection of time series, which can reveal anomalies beyond sudden and significant events, such as anomalous trends and gradual drifts. Such methods typically require an appropriate similarity measure [16]. Through appropriate combination with state-of-the-art similarity-based models, these methods can identify potential anomalous time series and cluster similar trends. Implementing such methods in a time varying setting could even help detect change points or anomalous events in individual time series as well as identifying anomalous time series [5, 31]. However, these methods are typically unable to scale to long time series [4, 31].

In this paper, we propose a new anomaly detection algorithm called Large deviations Anomaly Detection (LAD), for large/high-dimensional data and multivariate time series data. LAD uses the rate function from large deviations principle (LDP) [14, 27, 28] to deduce anomaly scores for the underlying data. Core ideas for the algorithm are inspired from large deviation theory’s projection theorem that allow better handling of high dimensional data. Unlike most high dimensional anomaly detection models, LAD does not incorporate feature selection or dimensionality reduction, which makes it ideal to study multiple time series in an online mode. The intuition behind the LAD model allows it to naturally segregate the anomalous observations at each time step while comparing multiple multivariate time series simultaneously. The key contributions of this paper are following:

1. We propose the Large deviations Anomaly Detection (LAD) algorithm, a novel and highly scalable LDP based methodology, for scoring based anomaly detection.
2. The proposed LAD model is capable of analyzing large and high dimensional datasets without additional dimensionality reduction procedures thereby allowing more accurate and cost effective anomaly detection.
3. An online extension of the LAD model is presented to detect anomalies in an multivariate time series database using an evolving anomaly score for each time series. The anomaly score varies with time and can be used to track developing anomalous behavior.
4. We perform an empirical study on publicly available anomaly detection benchmark datasets to analyze robustness and performance of the proposed method on high dimensional and large datasets.
5. We present a detailed analysis of COVID-19 trends for US counties where we identify counties with anomalous behavior (See Figure 1 for an illustration).

The rest of this document is organized as follows. Section 2 provides an overview of relevant existing methods for anomaly detection. Section 3 is a short background on underlying large deviations theory motivating LAD. Section 4 details our LAD model for detecting unsupervised anomalies in multivariate time series. Section 5 describes the experiments and demonstrate the state-of-the-art performance of our method. Section 6 concludes the paper and sketches direction for possible future work.

1In early November, these counties in North Dakota were exhibiting infection rates that were six times the national rate - https://www.washingtonpost.com/opinions/2020/11/06/north-dakota-covid-19-cases/
(a) Total Confirmed Cases

(b) Total Deaths

Figure 1: Top 5 anomalous counties identified by the proposed LAD algorithm based on the daily multivariate time-series, consisting of cumulative COVID-19 per-capita infections and deaths. At any time-instance, the algorithm analyzes the bi-variate time series for all the counties to identify anomalies. The time-series for the non-anomalous counties are plotted (light-gray) in the background for reference. For the counties in North Dakota (Burleigh and Grand Forks), the number of confirmed cases (top), and the sharp rise in November 2020, is the primary cause for anomaly 1. On the other hand, Wayne County in Michigan was identified as anomalous primarily because of its abnormally high death rate, especially when compared to the relatively moderate confirmed infection rate.

2 RELATED WORK

In this section, we provide a brief overview of relevant anomaly detection methods which have been proposed for high-dimensional data and for multivariate time-series data. We also discuss other works that have used the large deviations principle for detecting anomalies.

A large body of research exists on studying anomalies in high dimensional data [1, 3] but challenges remain. Many anomaly detection algorithms use dimensionality reduction techniques as a pre-processing step to anomaly detection. However, many high dimensional anomalies can only be detected in high dimensional problem settings and dimensionality reduction in such settings can lead to false negatives. Many methods exist that identify anomalies on high-dimensional data without dimensional reduction or feature selection, e.g. by using distance metrics. Elliptic Envelope (EE) [25] fits an ellipse around data centers by fitting a robust covariance estimates. Isolation Forest (I-Forest) [19] uses recursive partitioning by random feature selection and isolating outlier observations. $k$ nearest neighbor outlier detection (kNN) [23] uses distance from nearest neighbor to get anomaly scores. local outlier factor (LOF) [7] uses deviation in local densities with respect to its neighbors to detect anomalies. $k$-means--- [12] method uses distance from nearest cluster centers to jointly perform clustering and anomaly detection. Concentration Free Outlier Factor (CFOF) [2] uses a “reverse nearest neighbor-based score” which measures the number of nearest neighbors required for a point to have a set proportion of data within its envelope. In particular, methods like I-Forest and CFOF are targeted towards anomaly detection in high dimensional datasets.

In most settings, real time detection of anomalies is needed to dispatch necessary preventive measures for damage control. Such problem formulation requires collectively monitoring a high dimensional time series database to identify anomalies in real time. Recently, large deviations theory has been widely applied in the fields of climate models [13], statistical mechanics [26], networks [22], etc. Specially for analysis of time series, the theory of large deviations has proven to be of great interest over recent decades [6, 21]. However, these methods are data specific, often study individual time series and are difficult to generalize to other areas of research.

Anomaly detection for time series have been extensively explored in the literature [17], though most focus has been on identifying anomalous events in a single time-series. While, the task of detecting anomalous time series in a collection of time series has been studied in the past [10, 11, 29], most of these works have focused on univariate time series and have not shown to scale to long time series data. Our proposed method addresses this issue by using the large deviation principle.

3 LARGE DEVIATION PRINCIPLE

Large deviations theory provides techniques to derive the probability of rare events that have an asymptotically exact exponential approximation [14, 27, 28]. In this section, we briefly go over the large deviation theory and different ways to generate the rate functions required for the large deviations principle.

2In our context, these rare events include outlier/anomalous behaviors.
The key concept of this theory is the Large Deviations Principle (LDP). The principle describes the exponential decay of the probabilities for the mean of random variables. The rate of decay is characterized by the rate function $I$. The theorem is detailed below:

**Theorem 3.1.** A family of probability measures $\{\mu_n\}_{n \geq 0}$ on a Polish space $X$ is said to satisfy large deviation principle (LDP) with the rate function $I : X \rightarrow [0, \infty)$ if:

1. $I$ has compact level sets and is not identically infinite
2. $\liminf_{n \rightarrow 0} \epsilon \log \mu_n(O) \geq -I(O) \quad \forall O \subseteq X$ open sets
3. $\limsup_{n \rightarrow 0} \epsilon \log \mu_n(C) \leq -I(C) \quad \forall C \subseteq X$ closed sets

where, $I(S) = \inf_{x \in S} I(x), \ S \subseteq X$.

To implement LDP on known data with known distributions, it is important to decipher the rate function $I$. Cramer’s Theorem provides the relation between the rate function $I$ and the logarithmic moment generating function $\Lambda$.

**Definition 3.2.** The logarithmic moment generating function of a random variable $X$ is defined as

$$\Lambda(t) = \log E[\exp(tX)]$$

**Theorem 3.3 (Cramer’s Theorem).** Let $X_1, X_2, \ldots, X_n$ be a sequence of iid real random variables with finite logarithmic moment generating function, e.g. $\Lambda(t) < \infty$ for all $t \in \mathbb{R}$. Then the law for the empirical average satisfies the large deviations principle with rate $\epsilon = 1/n$ and rate function given by

$$I(x) = \sup_{t \in \mathbb{R}} (tx - \Lambda(t)) \quad \forall t \in \mathbb{R}$$

(2)

Thus, we get,

$$\lim_{n \rightarrow \infty} \frac{1}{n} \log \left( p \left( \sum_{i=1}^{n} X_i \geq nx \right) \right) = -I(x), \quad \forall x > E[X_1]$$

(3)

For more complex distributions, identifying the rate function using logarithmic moment generating function can be challenging. Many methods like contraction principle and exponential tilting exist that extend rate functions from one topological space to another. Using logarithmic moment generating function, e.g. $\Lambda(t) = \log E[\exp(tX)]$, we can use the rate function for Gaussian data where $\mu_n = \mathbb{N} \sigma_n^{-1} N$ and $\sigma_n$ is the sample standard deviation of $X_n$. Thus, the probability of the sample mean is $p$ is given by:

$$P(\bar{X} = p) \approx e^{-n\bar{X}^2}$$

(4)

Now, in presence of an anomalous observation $x_a$, the sample mean is shifted by approximately $x_a/n$ for large $n$. Thus, the probability of the shifted mean being the true mean is given by:

$$P(\bar{X} = x_a/n) \approx e^{-x_a^2/2n}$$

(5)

However, for large $n$ and $|x_a| << 1$, the above probabilities decay exponentially which significantly reduces their effectiveness for anomaly detection. Thus, we use $\frac{x_a^2}{2n}$ as an anomaly score for our model. Thus generalizing this, the anomaly score for each individual observation is given by:

$$a_i = nI(x_i) \quad \forall i \in \{1, 2, \ldots, n\}$$

(6)

4.4 Large Deviations for Anomaly Detection

Our approach uses a direct implementation of LDP to derive the rate function values for each observation. As the theory focuses on extremely rare events, the raw probabilities associated with them are usually very small [14, 27, 28]. However, the LDP provides a rate function that is useful as a scoring metric for our LAD model.

Consider a dataset $X$ of size $n$. Let $a = \{a_1, \ldots, a_n\}$ and $I = \{I_1, \ldots, I_n\}$ be anomaly score and anomaly label vectors for the observations respectively such that $a_i \in \{0, 1\}$ and $I_i \in \{0, 1\}$ \forall $i \in \{1, 2, \ldots, n\}$.

By large deviations principle, we know that for a given dataset $X$ of size $n$, $P(\bar{X} = p) \approx e^{-nI(p)}$. Assuming that the underlying data is standard Gaussian distribution with mean 0 and variance 1, we can use the rate function for Gaussian data where $I(p) = \frac{p^2}{2}$. Then the resulting probability that the sample mean is $p$ is given by:

$$P(\bar{X} = p) \approx e^{-n\bar{X}^2/2}$$

(4)

Now, in presence of an anomalous observation $x_a$, the sample mean is shifted by approximately $x_a/n$ for large $n$. Thus, the probability of the shifted mean being the true mean is given by:

$$P(\bar{X} = x_a/n) \approx e^{-x_a^2/2n}$$

(5)

4.2 LDP for High Dimensional Data

High dimensional data pose significant challenges to anomaly detection. Presence of redundant or irrelevant features act as noise making anomaly detection difficult. However, dimensionality reduction can impact anomalies that arise from less significant features.
of the datasets. To address this, we use the Dawson-Gärtner Projective theorem in LAD model to compute the rate function for high-dimensional data. The theorem records the maximum value across all projections which preserves the anomaly score making it optimal to detect anomalies in high-dimensional data. The model algorithm is presented in Algorithm 1.

**Algorithm 1:** Algorithm 1: LAD Model

**Input:** Dataset $X$ of size $(n, d)$, number of iterations $N_{iter}$, threshold $th$.

**Output:** Anomaly score $s$

**Initialization:** Set initial anomaly score and labels $a$ and $I$ to zero vectors and, entropy matrix $E = 0_{(n, d)}$ where $0_{(n, d)}$ is a zero matrix of size $(n, d)$.

for each $s \rightarrow 1$ to $N_{iter}$ do

1. Subset $X_{sub} = X[i == 0]$.
2. $X_{normalized}(:, d_i) = \frac{X(:, d_i) - X_{sub}(:, d_i)}{\text{cov}(X_{sub}(:, d_i))}$, $\forall d_i \in \{1, \ldots, d\}$.
3. $E[i, :) = -X_{normalized}[i, :)^2/2n$, $\forall i$.
4. $a_i = \max(E[i, :])$.
5. $a = \text{max(a)} - \text{min(a)}$.
6. $th = \text{min(th, quantile(a, 0.95))}$.
7. $I_i = 1$ if $a_i > th$, $\forall i$.

4.3 LAD for Time Series Data

The definition of an anomaly is often contingent on the data and the problem statement. Broadly, time series anomalies can be categorized to two groups [10]:

1. **Divergent trends/Process anomalies:** Time series with divergent trends that last for significant time periods fall into this group. Here, one can argue that generative processes of such time series could be different from the rest of the non-anomalous counterparts.

2. **Subsequence anomalies:** Such time series have temporally sudden fluctuations or deviations from expected behavior which can be deemed as anomalous. These anomalies occur as a subsequence of sudden spikes or fatigues in a time series of relatively non-anomalous trend.

The online extension of the LAD model is designed to capture anomalous behavior at each time step. Based on the mode of analysis of the temporal anomaly scores, one can identify both divergent trends and subsequence anomalies. In this paper, we focus on the divergent trends (or process anomalies). In particular, we try to look at the anomalous trends in COVID-19 cases and deaths in US counties. Studies to collectively identify divergent trends and subsequence anomalies is being considered as a prospective future work.

In this section, we present an extension of the LAD model to multivariate time series data. Here, we wish to preserve the temporal dependency as well as dependency across different features of the time series. Thus, as shown in Algorithm 2, a horizontal stacking of the data is performed. This allows collective study of temporal and non-temporal features. To preserve temporal dependency, the anomaly scores and labels are carried on to next time step where the labels are then re-evaluated.

**Algorithm 2:** Algorithm 2: LAD for Time series anomaly detection

**Input:** Time series dataset $\{t_{n,t}\}_{n=1}^N$ of size $(N, T, d)$, number of iterations $N_{iter}$, threshold $th$, window $w$.

**Output:** An array of temporal anomaly labels $l$

**Initialization:** Set initial anomaly score and labels $a$ and $I$ to zero matrices of size $(N, T)$ and, entropy matrix $E$ to a zero matrix of size $(N, T, d)$.

for each $t \rightarrow 1$ to $T$ do

$X = \text{hstack}(t_{n,t})$ where $t_{n,t} = \{t_{n,t-w, \ldots, t_{n,t}}\}$

$I[i, t] = I[i, t-1]$

$a[:, t] = a[:, t-1]$

for each $s \rightarrow 1$ to $N_{iter}$ do

1. Subset non-anomalous time series $X_{sub} = \{X[i, :]|I[i, t] == 0, vi\}$.
2. $X_{normalized}(i, :d_i) = \frac{X(i, :d_i) - X_{sub}(i, :d_i)}{\text{cov}(X_{sub}(i, :d_i))}$, $\forall d_i \in \{1, 2, \ldots, d + w\}$.
3. $E[i, :] = -X_{normalized}[i, :)^2/2n$, $\forall i$.
4. $a[i, t] = \max(E[i, :])$.
5. $a[:, t] = \text{max(a[:, t])} - \text{min(a[:, t])}$.
6. $th = \text{min(th, quantile(a[:, t], 0.95))}$.
7. $I[i, t] = 1$ if $a[i, t] > th$, $\forall i$.

As long term anomalies are of interest, time series with temporally longer anomalous behaviors are ranked more anomalous. The overall time series anomaly score $A_n$ for each time series $t_n$ can be computed as:

$$A_n = \frac{\sum_{t=1}^{T} I[n, t]}{T} \forall n$$

For a database of time series with varying lengths, the time series anomaly score is computed by normalizing with respective lengths.

5 EXPERIMENTS

In this section, we evaluate the performance of the LAD algorithm on multi-aspect datasets. The following experiments have been conducted to study the model:

1. **Anomaly Detection Performance:** LAD’s ability to detect real-world anomalies as compared to state-of-the-art anomaly detection models is evaluated using the ground truth labels.
2. **Handling Large Data:** Scalability of the LAD model on large datasets (high observation count or high dimensionality) are studied.
3. **Speed:** The computation and execution times of different algorithms are studied and evaluated.
4. **COVID-19 Time Series Data:** We study the performance of LAD model on multiple multivariate time series datasets to identify anomalous instances within each time step as well anomalous time series amongst many.
5.1 Datasets
We consider a variety of publicly available benchmark data sets from Outlier Detection DataSets /ODDS [24] (See Tables 1) for the experimental evaluation. For the time series data, we use COVID-19 deaths and confirmed cases for US counties from John Hopkins COIVD-19 Data Repository [15].

5.2 Baseline Methods and Parameter Initialization
As described in Section 4, LAD falls under unsupervised learning regime targeted for high dimensional data, we do not compare with supervised algorithms. For this we consider Elliptic Envelope (EE) [25], Isolation Forest (I-Forest) [19]3, local outlier factor (LOF) [7], and Concentration Free Outlier Factor CFOF [2]. The CFOF and LOF models assign an anomaly score for each data instance, while the rest of the methods provide an anomaly label. As above mentioned methods have one or more user-defined parameters, we investigated a range of values for each parameter, and report the best results. For Isolation Forest, Elliptic Envelope and CFOF, the contamination value is set to the true proportion of anomalies in the dataset.

The LAD model relies on a threshold value to classify observations with scores the value as strictly anomalous. Though this value is iteratively updated, an initial value is required by the algorithm. In this paper, the initial threshold value for the experiment is set to 0.95 for all datasets.

All the methods for anomaly detection benchmark datasets are implemented in Python and all experiments were conducted on a 2.7 GHz Quad-Core Intel Core i7 processor with a 16 GB RAM.

Table 2: Comparing LAD with existing anomaly detection algorithms for large/ high dimensional datasets using ROC-AUC as the evaluation metric.

| Data          | LOF | I-Forest | EE | CFOF | LAD |

| SPEECH        | 0.5  | 0.53     | 0.51 | 0.47 | 0.47 |

5.3 Evaluation Metrics
As LAD is an score based algorithm, we study the ROC curves by comparing the True Positive Rate (TPR) and False Positive Rate (FPR), across various thresholds. The final ROC-AUC (Area under the ROC curve) is reported for evaluation. For time series anomaly detection, we present the final outliers and study their deviations from normal baselines under different model settings.

5.4 Anomaly Detection Performance
Table 2 shows the performance of LOF, I-Forest, EE, CFOF and LAD on anomaly detection benchmark datasets. Due to relatively large run-time4, CFOF results are shown for datasets with samples less than 10k. For all the listed algorithms, results for best parameter settings are reported. The proposed LAD model outperforms other methods on most data sets. For larger and high-dimensional datasets, it can be seen from Table 2 that the LAD model outperforms all the models in most settings.5

To study the LAD model’s computational effectiveness, we study the computation time and scaling of LAD model on large and high dimensional datasets. We consider datasets with more than 10k observations or over 100 features for our analysis. Figures 2 and 3 show the computation time in seconds for benchmark datasets. It can be seen that the LAD model is relatively low computation time second only to Isolation Forest in most datasets. In fact, the computation time is more stable for our model as opposed to others in high dimensional datasets.

Figure 4 shows the scalability of LAD with respect to the number of records in the data. We plot the time needed to run on the first k records of the KDD-99 dataset. Each record has 29 dimensions. Figure 5 shows the scalability of LAD with respect to the number of dimensions (linear-scale). We plot the time needed to run on the first 1, 2, ..., 29 dimensions of the KDD-99 dataset. The results

4The CFOF model is computationally expensive relative to the rest of the algorithms. As it is aimed to study high-dimensional data, only results on datasets with <10k observations are presented.
5The lowest AUC values for the LAD model are observed for Speech and Optdigits data where multiple true clusters are noted.
Figure 2: Computation time for large datasets

Figure 3: Computation time for high dimensional datasets

Figure 4: LAD scales linearly with the number of records for KDD-99 data

Figure 5: LAD scales linearly with the number of dimensions in KDD-99 data.
cases, Hall (NE)\(^7\) in Figures 6a-6b, and Randal (TX) in Figures 9a-9b were identified anomalous due to their the deviant confirmed case trends which significantly contributed to the anomaly scores. This setting enables identification of time-series with at least one deviating feature.

Similarly, in Figures 6c and 6d, Wayne, Michigan along with Rockland, Richmond, Queens and Bronx in NY have been identified as anomalous. In particular, Michigan was seen to have 3rd highest deaths after NY and NJ in the early stages of the pandemic with Detroit metro-area contributing to most cases\(^8\). Though Wayne county has near normal trend in total confirmed cases where as the total deaths trend has deviated significantly.

**Daily New vs Total Counts.** Figures 7 and 9, show anomalous trends in multivariate time series for total and daily new counts respectively. It can be seen that the anomaly score is erratic for multivariate time series on new case counts. This is due to the fact that the data for new case and death counts is more erratic leading to fluctuating normal average as well as non-smooth anomaly scores.

---

The LAD model on the daily new counts data was able to capture the escalation in Greater Boston area, Essex, Massachusetts in Figure 9a and 9b during March 2020. Though the total trends seem to be normal, the multiple anomalous daily trends led to their high anomaly scores. Similar patterns led to identification of Lincoln...
Uniform Length vs Varying Length Time Series. The US county cases and deaths data consists of time series of uniform lengths. However, not all counties have events recorded in the early stages. Thus, studying the non-synchronized database creates a bias against counties with early reported cases. This can be seen in Figures 6 where counties like Wayne, Michigan are flagged anomalous despite starting after many counties in NY and NJ unlike in Figures 7 which reports counties in NY with an early start\(^9\). Similarly, Putnam (WV) and Laramie (WY) are found anomalous in Figure 10b where the recently evolved death trends show signs of significant divergence. On the other hand, Potter (TX) and Anderson (TX) have been identified anomalous in Figures 11a due to early increase in June 2020.

6 CONCLUSION

In this paper, we propose LAD, a novel scoring algorithm for anomaly detection in large/high-dimensional data. The algorithm successfully handles high dimensions by implementing large deviation theory. Our contributions include reestablishing the advantages of large deviations theory to large and high dimensional datasets. We also present an online extension of the model that is aimed to identify anomalous time series in a multivariate time series data. The model shows vast potential in scalability and performance against baseline methods. The online LAD returns a temporally evolving score for each time series that allows us to study the deviations in trends relative to the complete time series database.

A potential extension to the model could include anomalous event detection for each individual time series. Another possible future work could be extending the model to enable anomaly detection in multi-modal datasets. Additionally, the online LAD model could be enhanced to use temporally weighted scores prioritizing recent events.
