(Dated: 1st August 2018)

We are able to detect clear signatures of dephasing – a distinct trait of many-body localisation (MBL) – via the dynamics of two-site entanglement, quantified through the concurrence. Using the protocol implemented by M. Schreiber et al. [Science 349, 842 (2015)], we show that in the MBL phase the average two-site entanglement decays in time as a power law, while in the Anderson localised phase it tends to a plateau. The power-law exponent is not universal and displays a clear dependence on the interaction strength. This behaviour is also qualitatively different from the ergodic phase, where the two-site entanglement decays exponentially. All the results have been obtained by means of time-dependent density matrix renormalisation group simulations, and further corroborated by analytical calculations on an effective model. Two-site entanglement has been already measured in cold atoms: our analysis paves the way for the first direct experimental test of many-body dephasing in the MBL phase.

I. INTRODUCTION

The phenomenon of many-body localisation1-3 (MBL) refers to the breakdown of ergodicity in generic disordered many-body systems, due to quantum effects. This is a striking counterexample to the fundamental assumptions of statistical mechanics about the thermalisation of an isolated system. For any non-integrable classical many-body Hamiltonian system, the dynamics is ergodic in phase space, eventually leading to thermalisation. This occurs even for systems close to integrability via Arnold diffusion, a phenomenon strictly related to the celebrated KAM theorem4,5. In quantum systems there is a striking exception: destructive interference between matter waves forbids a system in the MBL phase to thermalise. Quantum effects make the system non-ergodic: no part of it acts as reservoir for the rest of the system.

At first glance, the existence of MBL is astonishing: due to the presence of interactions, one expects the quantum system to be non-integrable and to display ergodicity and thermalisation.6 This behaviour is however strange only apparently: indeed a system in the MBL phase can be mapped into an integrable system with an extensive number of local integrals of motion7-10. Traditionally, integrable systems are isolated points in the space of Hamiltonians, both from a classical14 and a quantum15 perspective; on the opposite, in MBL, integrability and non-ergodicity do not require any fine tuning. Remarkably, MBL has been recently conjectured to occur even in systems without disorder12,13; the contrast with the behaviour of classical systems is even more striking.

In some sense, the MBL phase is the continuation of the Anderson localised (AL) phase14,15 of non-interacting particles, when interactions are turned on: the two phases share several properties, mainly the absence of transport of any physical quantity. At the same time MBL has distinct features that make it qualitatively different from Anderson localisation. From one hand, while transport is frozen, correlations can still propagate in the MBL phase. This gives rise to a non-trivial dynamics of entanglement which is absent in the AL phase and which we will better discuss later. From the other hand, the transition to the MBL phase does not emerge in thermodynamic quantities, but rather in transport and time-correlation functions. This is indeed a dynamical transition, which requires appropriate observables in order to be identified. These very special properties have been recognised thanks to a constantly growing theoretical activity, whose aims are elucidating the distinguishing features of MBL and finding ways to detect them in the experiments.

Several works have characterised the MBL phase by: the absence of transport of charge, spin, mass1,16-18 or energy19; an emergent robust integrability7-10,20; a logarithmically slow but unbounded growth of entanglement21-23; a peculiarly sparse structure of eigenfunctions24,25; the behaviour of observables after a quantum quench26,27; the persistence of area law for entanglement up to arbitrary temperatures and for eigenstates of arbitrary energy in the spectrum3,16,28,29; the ability to protect discrete symmetries31 even at infinite temperature. A comprehensive description of this activity can be found in the reviews [3 and 32]. At the same time several different proposals have been put forward in order to experimentally detect MBL. We quote, for example, the interferometric probe based on coherent spin manipulations33, the search for revivals of the magnetisation34 or the temporal fluctuations around stationary values of local observables27.

The intense theoretical efforts of the last decade stimulated an exciting race towards its experimental verification. Last year the first beautiful experiments providing evidence of MBL appeared in cold atomic systems35,36 and trapped ions37. However, it is still debatable whether unique features of MBL, which are not present in AL systems, have been observed or not: experiments have focused on the propagation of particles which are frozen...
in both phases. It would be highly desirable to have a direct experimental test discriminating between these two cases, in order to probe the MBL dephasing mechanism. From a theoretical perspective, several different observables/protocols have been proposed to this aim (see above), but, in many cases, they are difficult to be implemented experimentally. The purpose of this paper is to overcome these difficulties: we analyse in detail a probe of MBL, which is able to discriminate it from the AL phase and is experimentally accessible within the existing technology. We are going to show that this probe is the two-site entanglement.

The dynamics of two-site entanglement has been recently measured in optical lattices and in trapped ions, respectively in Refs. [38] and [39]. The experiment of Fukuhara et al.\textsuperscript{38} considers a system of atoms governed by a Bose-Hubbard Hamiltonian. The spins of atoms are initially in a ferromagnetic phase: after flipping a spin at a given site (local quench protocol), the entanglement between neighbouring spins is measured as a function of time. As we are going to discuss in detail, we consider a slight modification of this quench protocol, namely the one implemented in Ref. [35]. Using this approach, and measuring both the imbalance and the two-site entanglement, we are able to extract the key properties of MBL phase. In particular, we can highlight clear differences with the AL phase in the measure of the two-site entanglement.

Entanglement plays an important role in MBL. While transport (of energy, spin, mass or other macroscopically conserved quantities) is frozen both in MBL and in AL phases, quantum correlations can still propagate in the MBL phase, giving rise to entanglement between distant sites of the system. In this context, the mapping of any MBL system to an integrable system with an extensive number of local integrals of motion is crucial. Thanks to this mapping, even in the absence of transport, when \textit{populations} in every site are stationary, it can be shown that \textit{coherences} of distant sites evolve in a non-trivial way (more details are in Sec. V). This phenomenon is defined as many-body dephasing: it is ultimately responsible for the unbounded (but slow) growth of the entanglement entropy. The situation in the AL phase is very different. In this case, the propagation of correlations and the entanglement growth stop after a while. Several studies (see, e.g., Refs. [21–23, 40–44]) have analysed the evolution of the entanglement entropy of large blocks in disordered spin chains. Its logarithmic growth\textsuperscript{21–23}, intimately related to the existence of an extensive number of local integrals of motions, has been identified as a unique trait of MBL. However, despite recent very interesting progresses\textsuperscript{45}, the entanglement block-entropy is very hard to be measured in a many-body context (virtually impossible on increasing the block size). On the opposite, the two-site entanglement we are considering here is directly accessible in cold-atom experiments.

This paper is organised as follows. In the next section we introduce the model and the quench protocol we are going to simulate. Both are chosen to be essentially identical to those implemented in the experiment of Ref. [35]. The two-site entanglement will be quantified through the concurrence defined in Sec. III. Section IV contains the results of our density matrix renormalisation group simulations. They show that the MBL phase is characterised by a typical power-law decay of the concurrence. This behaviour strongly contrasts with AL, where the concurrence reaches a non-vanishing stationary value; it is also very different from the ergodic phase, where the concurrence abruptly vanishes after a short transient. We are able to study how the AL phase is reached as a vanishing-interaction limit of the MBL: the power-law decay of the concurrence starts after a stationary, metastable, plateau whose extension in time diverges as a power law when the interaction vanishes. In Sec. V, we show that this power-law behaviour is reproduced by a phenomenological integrable model of interacting qubits (the so-called “$t$-bit model”): this agrees with the fact that our MBL system can be mapped into an integrable system. In Sec. VI, we discuss a number of additional effects (the role of number fluctuations, finite temperature, control of laser pulses) that may arise when measuring entanglement from experimental data. We also provide a (more easily measurable) bound to the concurrence, which gives very accurate results and faithfully reproduces the essential phenomenology. Finally, Sec. VII is devoted to our conclusions and perspectives for future work.

\section{THE MODEL}

We consider a generalisation of the Aubry-André model\textsuperscript{46}, which can be realised be means of a two-species Bose-Hubbard model in the presence of a periodic potential incommensurate with the lattice spacing. This kind of potential is also defined as quasi-periodic, pseudorandom or Aubry-André potential. In the limit in which the on-site interaction is dominant with respect to the hopping, fluctuations in the number of particles on each site are frozen. It is then possible to derive an effective Hamiltonian in the subspace where the occupation is fixed to one particle per site. Here the dynamics is governed by a spin-$1/2$ XXZ Hamiltonian\textsuperscript{47,48} where the two eigenstates of $\hat{S}_j^z$ represent the occupation of the $j$th site by one of the two species (here $\hat{S}_j^\alpha \equiv \hat{\sigma}_j^\alpha /2$, where $\hat{\sigma}_j^\alpha$ are the usual Pauli matrices on site $j$, with $\alpha = x,y,z$). In the presence of an Aubry-André potential, the effective spin model also includes an inhomogeneous magnetic field leading to the Hamiltonian

\[
\hat{H} = - \sum_j \left[ J(\hat{S}_j^+ \hat{S}_{j+1}^- + \text{H.c.)} + V \hat{S}_j^z \hat{S}_{j+1}^z \right] + \Delta \sum_j \left[ \cos(2\pi \beta j + \phi) \hat{S}_j^z \right],
\]  

(1)
where \( \hat{S}^\pm = \hat{S}^x \pm i\hat{S}^y \) are the raising/lowering operators. The third term in Eq. (1) is due to the external quasi-periodic on-site potential: the coupling strength appears as the parameter \( \Delta \), the inverse of the incommensurate wavelength as an irrational number \( \beta \), and \( \phi \) is a phase. In the following, we will consider a one-dimensional optical lattice with \( L \) sites and open boundary conditions.

Equation (1) can be mapped, via a Jordan-Wigner transformation, onto a spinless fermionic Hubbard model with a quasi-periodic Aubry-André chemical potential:

\[
\hat{H} = -\sum_j \left[ J(\hat{\alpha}_j^\dagger \hat{\alpha}_{j+1} + \text{H.c.}) + V \hat{n}_j \hat{n}_{j+1} \right] + \Delta \sum_j \left[ \cos(2\pi \beta j + \phi) \hat{n}_j \right],
\]

where \( \hat{\alpha}_j^{(t)} \) is the annihilation (creation) fermion operator, \( \hat{n}_j = \hat{\alpha}_j^\dagger \hat{\alpha}_j \) the local number operator, \( J \) the tunneling matrix element between neighbouring sites, and \( V \) the nearest-neighbour interaction. The existence of a MBL phase in this model was rigorously established in Ref. [49].

In the non-interacting case \((V = 0)\), when the amplitude \( \Delta \) of the quasi-periodic potential overcomes the threshold \( \Delta_c = 2 \), the system undergoes a transition from an ergodic to an AL phase\(^{16}\). This transition has been recently observed in a cold-atom experiment\(^{50}\). The interacting case \((V \neq 0)\) presents three distinct phases, depending on the choice of the coupling constants: ergodic, MBL, and AL phases. Although an accurate analysis of the phase diagram is not the aim of this work, we identified the parameters leading to the different phases, without however dwelling on the precise location of the phase boundaries. The resulting (approximate) phase diagram in the \( \Delta-V \) plane is reported in Appendix A.

In order to detect signatures of MBL in the two-site entanglement, we study its time-dependence after a quantum quench. The protocol we consider is the same as in Ref. [35]. We initialise the system in the Néel state

\[
|\psi(t = 0)\rangle = |\uparrow, \downarrow, \cdots, \uparrow, \downarrow\rangle.
\]

Then we follow the time evolution governed by Hamiltonian (1), working in the subspace with total conserved spin \( S^z_{\text{tot}} = \sum_j \hat{S}^z_j = 0 \). We average the quantities of interest over many realisations of pseudo-disorder, through a random sampling of the phase \( \phi \) in the on-site potential. Through the rest of the paper, we will fix the inverse wavelength of the quasi-random potential to \( \beta = 532/738 \). We make this choice because this is the better approximation to an irrational number which can be done in the experiments (it is the one used in Ref. [35]). We further set \( J = 1 \) and \( h = 1 \).

### III. TWO-SITE ENTANGLEMENT AND CONCURRENCE

In the model of Eq. (1), the entanglement between two sites can be quantified through the concurrence\(^{51}\). Let us consider two sites, \( i \) and \( j \), and define \( \rho_{i,j} \) as the reduced density matrix describing the subsystem formed by these two sites. The concurrence \( C_{i,j} \) measures the entanglement between the two spins located at \( i \) and \( j \), minimised over all the possible decompositions of the matrix

\[
\rho_{i,j} = \sum_{a=1}^4 p_a |\psi_a\rangle \langle \psi_a|,
\]

with arbitrary states \( |\psi_a\rangle \) and \( \sum_a p_a = 1 \) (with \( p_a \geq 0 \)). With this definition, it can be shown that\(^{51}\):

\[
C_{i,j} = \max \left\{ 0, \lambda^{(1)} - \lambda^{(2)} - \lambda^{(3)} - \lambda^{(4)} \right\},
\]

where \( \lambda^{(a)} \) are the square roots of the eigenvalues of the product matrix \( R = \rho_{i,j} \rho_{j,i} \), taken in descending order. The spin flipped matrix \( \tilde{\rho} \) is defined as \( \tilde{\rho} \equiv (\sigma^y \otimes \sigma^y) \rho^* (\sigma^y \otimes \sigma^y) \), where the complex conjugate is taken in the standard basis. If \( C_{i,j} = 0 \), then there is a decomposition of the reduced density matrix \( \rho_{i,j} \) in which all the states \( |\psi_a\rangle \) are separable. The concurrence has been employed several times to analyse many-body systems (see Ref. [52] for a review). Here we are going to show that its dynamics is able to distinguish between ergodic, MBL, and AL phases.

In the case we are considering, the total magnetisation \( S^z_{\text{tot}} \) along the \( z \)-axis is conserved: if we express \( \rho_{i,j} \) in the \( z \)-basis, we find a particularly simple block-diagonal form

\[
\rho_{i,j} = \begin{pmatrix}
P_{\uparrow\uparrow} & 0 & 0 & 0 \\
0 & P_{\uparrow\downarrow} & \rho_{\uparrow\downarrow} & 0 \\
0 & \rho_{\uparrow\downarrow} & P_{\downarrow\uparrow} & 0 \\
0 & 0 & 0 & P_{\downarrow\downarrow}
\end{pmatrix},
\]

where

\[
\begin{align*}
P_{\uparrow\uparrow} &= \langle (\frac{1}{2} + \hat{S}_i^x)(\frac{1}{2} + \hat{S}_j^x) \rangle, \\
P_{\uparrow\downarrow} &= \langle (\frac{1}{2} + \hat{S}_i^x)(\frac{1}{2} - \hat{S}_j^x) \rangle, \\
P_{\downarrow\uparrow} &= \langle (\frac{1}{2} - \hat{S}_i^x)(\frac{1}{2} + \hat{S}_j^x) \rangle, \\
P_{\downarrow\downarrow} &= \langle (\frac{1}{2} - \hat{S}_i^x)(\frac{1}{2} - \hat{S}_j^x) \rangle, \\
\rho_{\uparrow\downarrow} &= \langle \hat{S}_i^y \hat{S}_j^y + \hat{S}_i^x \hat{S}_j^y + i(\hat{S}_i^y \hat{S}_j^x - \hat{S}_i^x \hat{S}_j^y) \rangle.
\end{align*}
\]

(analogous expressions can be written in the fermionic representation). The concurrence can be analytically computed in this case:

\[
C_{i,j} = 2 \max \left[ 0, |\rho_{\uparrow\downarrow}| - \sqrt{P_{\uparrow\uparrow} P_{\downarrow\downarrow}} \right],
\]

thus reducing to a very simple form which only contains \( zz \) expectation values and a term \( |\rho_{\uparrow\downarrow}| \) which is proportional to the local spin current (and vanishes in the long-time limit, due to localisation). It is important to keep in mind this observation, in view of the analysis that will be presented in Sec. VI.
Because of the incommensurate potential, the concurrence (as well as other observables) will be site-dependent. To overcome this difficulty, we choose to analyse a single expression containing information on all the pairs of sites; namely, the square of the quasi-disorder average concurrence summed over the sites:

\[ C(t) = \sum_{i,j \in \text{bulk}} \left[ \sqrt{C_{i,j}(t)} \right]^2. \tag{7} \]

The bar indicates the quasi-disorder average which is performed over different realisations of \( \phi \); in order to avoid finite-size effects due to the edges, we restrict the summation over \( i \) and \( j \) to the bulk. Precisely, we consider \( L/3 \leq i, j \leq 2L/3 \). The quantity defined in Eq. (7) allows us to discuss in a compact way the results for the two-site entanglement. Moreover (together with the tangle) it allows to extract information on the residual multi-partite entanglement of the two selected sites\(^{53,54}\).

The behaviour of \( C(t) \) also reflects the so-called monogamy properties of entanglement: A given spin cannot be highly entangled with more than one other spin in the system. We will see that monogamy is useful to understand the results of this paper. For simplicity, in the rest of the presentation we will refer to the quantity \( C(t) \) of Eq. (7) as the concurrence.

The two-site entanglement is contained in the reduced density matrix \( \rho_{i,j} \), and consequently can be expressed through the different spin-spin correlations [see Eqs. (6)]. Temporal fluctuations around the stationary values of local, as well as two-spin observables, have been shown to decay as power laws\(^{27}\). Despite providing a good insight about the dynamics, a direct relation between the behaviour of the fluctuations and the concurrence cannot be drawn because entanglement results in a complex function of the correlators. In general it has been shown that, in most cases, the two-site entanglement is not directly related to the properties of correlation functions\(^{52}\).

Complementary to the entanglement analysis, we also study the time evolution of the imbalance in the occupation between even (\( e \)) and odd (\( o \)) sites\(^{35}\). In the particle representation, this is the difference in the occupation of even and odd sites \( I = (N_e - N_o)/(N_e + N_o) \); in the spin representation it is defined as

\[ I = \frac{\langle S^z_e \rangle - \langle S^z_o \rangle}{1 + \langle S^z_e \rangle + \langle S^z_o \rangle}. \tag{8} \]

The imbalance has been measured experimentally\(^{35,36}\); it has been observed that it tends asymptotically to a non-vanishing stationary value, both in the MBL and AL phases. As we are going to show, by analysing the time-dependence of \( I \) and of \( C \), we can distinguish between the three different phases. More importantly, we are also able to capture the subtle dephasing mechanisms occurring in the MBL phase.

**Figure 1.** Time evolution for the concurrence at distinct \( r = |i - j| \) distances, in a system with \( L = 24 \) sites, averaged over 16 pseudo-disorder realisations. We consider sites at the center of the lattice, precisely, \( r = 1 \leftrightarrow (i = L/2, j = L/2 + 1) \) and \( r = 2 \leftrightarrow (i = L/2 - 1, j = L/2 + 1) \). The top panel refers to the MBL phase, the bottom panel to the AL phase. In the ergodic phase the concurrence for \( r = 2 \) is several order of magnitude smaller than \( C_{r=1} \), and could not be distinguished from zero in the scale of the plot. The results are qualitatively similar if we consider different sites in the bulk. The parameters are \( \Delta = 3 \), \( V_1 = 1 \) for the top panel and \( \Delta = 4 \), \( V_1 = 0 \) for the bottom panel.

**IV. RESULTS**

This section will be entirely devoted to the discussion of the outcomes of our simulations, concerning the dynamics of the concurrence and the imbalance. In all the cases discussed here, we initially prepare the system in the state \( | \psi(t = 0) \rangle \) [see Eq. (3)] and we study its subsequent evolution. We choose Eq. (3) as it is most relevant for an experimental verification of our results. The choice of a different initial state should not present qualitative changes in the dynamics of our observables in the localised phase, as will become clear from the analysis of a phenomenological model in Sec.V. In order to have a better comparison with the existing results on the relation between many-body dephasing and growth of entanglement, we will also compare our results with the behaviour of the entropy. The message we would like to convey is that signatures of MBL that emerge in the entanglement entropy are evident also in the two-site entanglement, but the last object has the important advantage of being easier to access in experiments.

The dynamics of model (1) has been simulated using the time-evolving block decimation (TEBD) strategy on matrix product states\(^{55,56}\). We used a time step \( \Delta t \lesssim 0.1 \) (depending on the model parameters), a maximum bond dimension \( m = 200 \), and a Trotter order equal to 4, leading to negligible error thresholds for all the observables.
under analysis. In the specific case of non-interacting systems, however, we have evolved the state in time using the covariance matrix (to make use of the simplifications arising for quadratic Hamiltonians). We have also considered systems with different size, ranging from $L = 12$ to $L = 30$ for the interacting model ($V \neq 0$), and up to $L = 240$ for the non-interacting model ($V = 0$). We carefully verified that all the data presented below are robust with $L$ (provided $L \gtrsim 20$), and thus our claims do not suffer appreciable finite-size corrections. Further details on this issue are provided in Appendix D.

Since the definition of Eq. (7) involves a summation over many lattice points, it is useful to understand whether there are dominant contributions to the sum. This analysis is reported in Fig. 1, where the concurrence is plotted as a function of time for nearest-neighbour and next-nearest-neighbour lattice sites. The coupling constants are chosen in such a way to be in the AL (bottom) or MBL (top) phase. We did not plot similar curves for the ergodic phase as the next-nearest-neighbour concurrence could not be distinguished from zero on the scale of the plot. In all the phases, the concurrence between sites distant more than two lattice constants is essentially negligible or vanishing. We believe that this behaviour could be indirectly linked to the properties of the eigenstates of Hamiltonian (1), which display an exponential decay of the concurrence with the distance between sites\textsuperscript{57}. Therefore, although we use the definition in Eq. (7), it is useful to keep in mind that the results we are going to present in the rest of the section essentially reflect the behaviour of the nearest-neighbour concurrence. We also remark that our results are robust with respect to pseudo-disorder averages, in the sense that the error induced by such averaging is barely visible on the scale of the various figures, and does not affect our conclusions (see Appendix D for a more detailed discussion).

In the following subsections we will discuss in detail the dynamics of our system in the AL, MBL and ergodic phases.

A. Anderson localised phase

We first consider the case with $V = 0$. In the absence of interactions, the Hamiltonian reduces to a quadratic fermion model: its dynamics can be easily studied through the evaluation of the corresponding two-point correlation functions. In Fig. 2, the concurrence and the imbalance are plotted as a function of time for different disorder strengths. We only present the case $L = 24$, in order to be consistent with the numerical simulations of the interacting systems: we simulated even larger lattices lengths without seeing appreciable differences (see Appendix D). After a non-trivial transient, that will be discussed later, both the concurrence and the imbalance saturate oscillating around a stationary condition that depends on the value of $\Delta$. A key observation is that both of them roughly saturate at the same time: in the Anderson insulator the entanglement does not evolve in time, in the regime where the spin dynamics is frozen. We will see that in the MBL phase the behaviour is qualitatively different.

In analogy with the stationary value of the imbalance\textsuperscript{55}, the corresponding two-site entanglement is also larger on increasing $\Delta$ and moving deeper in the localised phase. This behaviour can be qualitatively understood as follows. Starting from the factorised state of Eq. (3), the short-time ($t \lesssim 1$) increase of entanglement is almost independent of $\Delta$ and is essentially due to the exchange coupling terms (the hopping in the fermion language) in Eq. (1). Due to the many-body dynamics, the two-site entanglement then starts to decrease until a time $t^*$, after which its subsequent dynamics is frozen. We find that $t^*$ decreases with $\Delta$ (Fig. 2, top panel): the larger is $\Delta$ (that is, the deeper the system is in the localised phase), the earlier the concurrence will freeze, attaining indeed a larger stationary value. The time at which the dynamics is frozen, $t^*$ should diverge when $\Delta \rightarrow 2$ as a power law, i.e.
We have observed that, after the initial dynamics ($t \sim 1$), the concurrence exhibits a small decay until its saturation. For later comparison with the MBL case, it is useful to have a closer look at this intermediate regime. To this aim we plot both the two-site entanglement (Fig. 2, top panel) and the block entropy (Fig. 3, bottom panel). Moreover, to better analyse the decay of the concurrence, we subtract its long-time value (Fig. 3, top panel). In this intermediate regime, both the entropy and the concurrence, as well as the imbalance, evolve in time: the system has not yet frozen. On the opposite, we will see in the MBL phase that the two-site entanglement shows a power-law decay only in the long-time limit and not in the intermediate regime. Moreover, in this asymptotic regime, the spin dynamics is frozen and MBL dephasing takes place. Therefore, the two power-law decays in the AL phase and in the MBL phase are different phenomena, which have to be distinguished from each other: the first one is a transient effect occurring before the entanglement and spin dynamics freeze, the second one is an asymptotic phenomenon occurring when the spin dynamics has already frozen. Another clear difference with the MBL phase emerges also in the decay of the concurrence to its long-time limit: apparently the exponent of the power law does not depend on the disorder strength (Fig. 3, top panel); we are going to see that the power-law decay in the MBL phase behaves very differently.

**B. Many-body localised phase**

Equipped with the results for the AL phase, we are now going to discuss what happens in the presence of interactions. We first consider parameters for which the system is in the MBL phase (see the phase diagram in Appendix A). As outlined in the introduction, the spin dynamics in the MBL phase is frozen but correlations evolve in time due to many-body dephasing which is connected to the existence of an extensive number of local integrals of motion. Such dephasing peculiarly affects the behaviour of the entanglement: a signature of this phenomenon can be seen in the evolution of the half-system entanglement entropy which increases logarithmically in time only in the MBL phase. We are going to show that signatures of these effects can also be seen in the two-site entanglement, which shows a very special long-time behaviour unique to the MBL phase.

In Fig. 4, we show the dynamical behaviour of the concurrence (top panel) and the imbalance (bottom panel) in the MBL phase. As previously discussed for the AL phase, also here the initial dynamics, up to $t \lesssim 1$, is independent of $\Delta$ and $V$: in this time regime, the only relevant terms of the Hamiltonian in Eq. (1) are those containing the exchange couplings.

The interesting regime occurs for longer times, $t \gtrsim 1$. In a region where the imbalance is already frozen, we clearly see a power-law decay for the concurrence with an exponent that depends both on $V$ and $\Delta$. This decay has to be contrasted with the saturation observed in the AL phase. Indeed we found that, in the presence of interactions, there is a regime where transport is absent but still the two-site entanglement evolves in time. It is important to stress that the dephasing mechanism which leads to the power-law decay of the two-site entanglement is the same as the one giving rise to the logarithmic growth of the entanglement entropy. We will discuss in detail this mechanism in Sec. V. The important new ingredient is that the two-site entanglement is “easy” to be measured. The comparison of Fig. 2 and Fig. 4 shows that,
is known that the mechanism for delocalisation (and in general for mixing distant spins with a local spin) is to construct long non-local operators which, at a variance with respect to the AL case, are not simply bilinear in the raising and lowering operators. Therefore the dynamics of one spin gets mixed with a line of spins of length $\xi_{\text{MBL}}$, that is the MBL localisation length. In this way, the statistics of recurrences of the concurrence (the times at which $C_{i,j}$ returns to be non-zero) is less regular than in the AL case: after averaging, this leads to the power-law decay.

C. Ergodic phase

We conclude this section by analysing the concurrence in the ergodic phase. In this case we consider interactions $V \gtrsim 1$. In this regime, TEBD simulations are more demanding, and we are able to follow the dynamics reliably only up to $t \sim 10$. In Fig. (5) (bottom panel) we show the imbalance as a function of time. In the ergodic phase it should go to zero in the long-time limit. As we can see, times $t > 10$ are needed for a full equilibration. However the data clearly show that the imbalance is still decaying towards its stationary value.

The behaviour of the concurrence (Fig. 5, top panel) qualitatively differs from the previous cases: here it vanishes abruptly. The data seem to indicate an exponential decay (especially visible for $\Delta = 0$). Due to the very fast decay, it is hard to unambiguously distinguish between an exponential and a high-order power-law decay. The ergodic phase is further characterised by large revivals with a typical period of the inverse of the exchange coupling. In the long time (stationary) limit, the concurrence is expected to vanish. The system will equilibrate to an effective temperature which is related to the energy initially injected in the system. This effective temperature is much larger than one (in units of $J$) for the choice of our initial states. At this temperature, any trace of thermal entanglement has already disappeared \cite{52}.

The different time-dependence in the decay of two-site entanglement is intimately connected to the monogamy of entanglement. Because of the much faster propagation of excitations in the ergodic phase, entanglement will spread faster. Consequently two-site entanglement will decay rapidly, that is, exponentially as observed in the simulations. The spread, and related decay in the concurrence, is slower in the MBL phase.

V. CONCURRENCE IN THE ℓ-BIT MODEL

In order to corroborate our numerical results, we are going to show that the above discussed phenomenology can be obtained by means of an effective model expressed in terms of the local integrals of motion. Within this effective model it is possible to obtain semi-analytical results and, most importantly, it is natural to link the

while the imbalance saturates both in the AL and MBL phases, the concurrence behaves qualitatively different in the two cases.

The differences between AL and MBL can be further highlighted in the weakly interacting limit $V \ll 1$. In this case, two regimes appear in the dynamics of concurrence. After the common transient, the concurrence reaches a plateau typical of the AL phase. The plateau occurs for times $1 \leq t \leq t_{\text{int}} \sim 1/V$ (for weak interactions it is possible to separate this time scale). Only at later times, $t \geq t_{\text{int}} \sim 1/V$, interactions set in and the concurrence starts to decay as a power law. A detailed analysis of this regime, together with the determination of $t_{\text{int}}$ as a function of the interaction $V$, is presented in Appendix B.

One final comment is in order. The results presented here are for the average two-site entanglement; its statistics is expected to be very interesting, as well. From perturbative constructions of the integrals of motion \cite{52}, it
Hamiltonian include $n$-body interactions, with $n > 2$, which, for simplicity, we will not consider here and are irrelevant for our purposes (see later). The spins $\hat{\tau}$ are local functions of the physical spins: the precise form of this mapping is not important for the present work. In an Anderson insulator, the couplings $J_{jl}$ are vanishing, and a set of independent non-interacting spins is sufficient for an effective description of the dynamics on a distance larger than the localisation length.

The analysis of the model in Eq. (9) gives us the possibility to see from a different perspective, and to clearly understand, the difference in the behaviour of the two-site entanglement between AL and MBL phases. From one side, the Hamiltonian of an Anderson insulator will only lead to single-bit rotations (that do not modify the entanglement). On the opposite, in the MBL phase, the second term of Eq. (9) is responsible for two-qubit gates (controlled phase-shifts) that lead to a time-dependence of the entanglement. These terms are the ones leading to the logarithmic growth of entropy (higher-order contributions to the Hamiltonian do not change the picture). We are going to show that they also lead to the power-law decay of the concurrence.

The dynamical protocol we consider goes as follows. The system is initially prepared in a generic separable state given by

$$\hat{H} = \sum_j h_j \hat{\tau}^z_j + \sum_{j \neq l} J_{jl} \hat{\tau}^z_j \hat{\tau}^z_l + \ldots$$

(9)

Here, $\{\hat{\tau}^z_j, \hat{\tau}^y_j, \hat{\tau}^x_j\}$ are the localised spin-1/2 operators associated to the local integrals of motion (in this context, they are also called the $\ell$-bit operators: "$\ell$" stands for localised). In the previous definition, $h_j$ are random fields, and $J_{jl} = W_{jl} e^{-\alpha |j-l|}$ are the interaction terms, with $W_{jl}$ assumed to be a random variable uniformly distributed in the range $[-W, W]$.

Further terms in the dynamics generated by the phenomenological $\ell$-bit model give a meaningful comparison with the exact dynamics of Hamiltonian (1) for times $t > 1$. In this time-regime, the interactions and the quasi-periodic Aubry-André potential become relevant (in the initial transient we saw that only the exchange terms affect the concurrence dynamics).

The dynamical protocol we consider goes as follows. The system is initially prepared in a generic separable state given by

$$|\psi_0\rangle = \otimes_{j=1}^L \left[ \cos(\phi_j) |\uparrow\rangle + e^{i\theta_j} \sin(\phi_j) |\downarrow\rangle \right]$$

Figure 5. Time-evolution for the concurrence (top) and the imbalance (bottom) in the ergodic phase. The system has $L = 24$ sites for $\Delta = 3$, $V = 1.5$, while it is slightly larger, having $L = 48$ sites, for $\Delta = 0$, $V = 2$. Our results are averaged over ~30 realisations of the pseudo-disorder. Black dashed lines in the top panel are a guide to the eye, to indicate the exponential decay.

Figure 6. Time-evolution for the concurrence in the $\ell$-bit model (9). The log-log scale highlights the power-law decay. We consider a system with $L = 72$ sites, and average over $10^2$ simulations where the initial state as well as the couplings in the Hamiltonian (9) are chosen randomly.
where \{\ket{\uparrow}, \ket{\downarrow}\} are the eigenstates of the $\hat{\tau}_j^z$ operator and $\phi_j, \theta_j$ are randomly chosen parameters. The time evolution of the $\ell$-bit operators can be easily computed (see Appendix C) and the concurrence can be determined as a function of time. In our analysis, we average over distinct initial states (different realisations of \{\theta_j\}, \{\phi_j\}), local disorder terms $h_j$ (despite it has absolutely no effect on the concurrence) and interacting terms $W_{ij}$.

As already mentioned, when we are in the AL phase, the Hamiltonian (9) induces a local dynamics: it cannot lead to any change in the entanglement. For the MBL phase the situation is much more intriguing, because of the coupling between the $\ell$-bit operators. Figure 6 displays the concurrence as a function of time, averaged over random realisations of the external fields, couplings and initial preparation of the state. We see that the concurrence decays as a power law, fully confirming the fact that this form of two-site entanglement behaviour is a typical feature of MBL.

VI. EXPERIMENTAL ISSUES AND A BOUND FOR THE CONCURRENCE

Experimentally, the detection of concurrence for unknown two-site reduced density matrices might face some imperfections, such as the lack of complete experimental control in the measurements, on-site number fluctuations or thermal smearing. For a better comparison with the experiments, it is important to consider all these issues.

The spin-model of Eq. (1) does not include number fluctuations, that are present in the native two-species Bose-Hubbard Hamiltonian. A detailed analysis of these effects has been performed in Ref. [59]. As long as the on-site repulsion between bosons is much larger than their hopping (in practice, a factor five in this ratio is enough) the predictions of the effective spin models are reliable. As far as thermal fluctuations are concerned, the analysis of Ref. [59] confirms that, as expected, our model is reliable for experiments if the temperature is of the order of few percents of the on-site interaction.

Here it is of particular importance to address the lack of control in the pulses that are needed to measure the entanglement: this fact leads to the detection of smaller correlation values. In connection with this issue, below we provide a very useful lower bound for the concurrence. For the present model, the qualitative behaviour of this bound agrees with the actual concurrence dynamics with high fidelity. For longer times the agreement becomes even quantitative, since the bound becomes tighter with increasing time.

A full two-site reduced density matrix can be obtained by measuring all its spin-spin correlation functions. In principle, such measurements could be performed in a cold-atom setup by first applying pulses on each individual spin site and then allowing it to freely rotate. After the appropriate time-interval has elapsed, the measurement is performed in a fixed basis (e.g., in the z-eigenstate basis \{\ket{\uparrow}, \ket{\downarrow}\}). However, in cold-atom implementations of Hubbard models, pulses on individual spin
sites are not yet implemented. In this case, only a global pulse on both spin sites is allowed, and consequently only measurements of spin-spin correlations along the same direction are performed. In this case, the reduced density matrix element $\rho_{\uparrow \downarrow}$ is approximated by

$$
\tilde{\rho}_{\uparrow \downarrow} = \langle \hat{S}_i^+ \hat{S}_j^- + \hat{S}_i^- \hat{S}_j^+ \rangle = \Re(\rho_{\uparrow \downarrow}). \tag{10}
$$

Recalling the expression for the concurrence (6), since $|\tilde{\rho}_{\uparrow \downarrow}| \leq |\rho_{\uparrow \downarrow}|$, we obtain the lower bound

$$
\tilde{C}_{i,j} \equiv 2 \max \left[ 0, |\tilde{\rho}_{\uparrow \downarrow}| - \sqrt{P_{\uparrow \downarrow} P_{\uparrow \downarrow}} \right] \leq C_{i,j}. \tag{11}
$$

Since the concurrence is generated essentially only between nearest-neighbour sites, let us focus on this case. Here, $\rho_{\uparrow \downarrow}$ has a particularly simple form, $\rho_{\uparrow \downarrow} = \langle \hat{a}_j^\dagger \hat{a}_{j+1} \rangle$, and a clear physical interpretation. As we can see in Eq. (10), the bound $\tilde{C}_{i,j}$ for the concurrence does not involve the imaginary parts of the hopping terms, which physically correspond to the spin current between the neighbouring sites $\propto \Im(\langle \hat{a}_j^\dagger \hat{a}_{j+1} \rangle)$. Since in the localised phase we should asymptotically expect no current (despite still having a flow of information/correlations), the above bound should become tighter with the increase of time. Precisely, $\tilde{\rho}_{\uparrow \downarrow} \sim \rho_{\uparrow \downarrow}$ for $t \gg 1$, and consequently $\tilde{C}_{i,j} \sim C_{i,j}$.

Figure 7 compares the dynamics of the concurrence (in colour) with its bound (grey) for the three different phases: AL (panels $a_1$ and $a_2$), MBL (panel b), and ergodic (panel c). It is evident that, except for the initial transient, the bound faithfully reproduces the behaviour of the two-site entanglement, thus making the experimental detection easier.

VII. CONCLUSIONS

The aim of this paper was to show that distinct features of the many-body localised phase can be detected through a measure of two-site entanglement. The time-dependence of the concurrence, the measure we used to quantify two-site entanglement, can clearly distinguish between MBL, AL and ergodic phases. In order to highlight this different behaviour, we studied the dynamics of two-site entanglement in a quantum quench, as experimentally implemented by Schreiber et al. in Ref. [35]. We stress the importance on the choice of the quantum correlation quantifier as well as in the initial state, since different choices could lead to distinct long-time behaviours.

Here we considered a two-species Bose-Hubbard model in an optical lattice, undergoing a quasi-periodic Aubry-André potential. Ignoring number fluctuations, this system reduces to the XXZ model, studied here. Our results were based on time-dependent density matrix renormalisation group simulations complemented by semi-analytical calculations on an effective model. After an initial transient, dominated by the kinetic term in the Hamiltonian, the concurrence dynamics in the different phases shows a strikingly different behaviour. The two-site entanglement saturates to a non-vanishing constant in the AL phase, while it decays as a power law in the MBL phase and exponentially fast in the ergodic one.

In order to corroborate the claim that the power-law decay is a characteristic trait of the MBL phase, we analysed the same problem using an integrable phenomenological $\ell$-bit model $3,7$, which is known to capture the essence of the MBL phase. This is a consequence of the unitary equivalence of any MBL system to an integrable one with localised integrals of motion. Exploiting the integrability of the phenomenological model, we could compute the two-site entanglement in a semi-analytical way, highlighting the same power-law decay occurring in the MBL phase of our system.

The main advantage of our proposal relies on the fact that experimental protocols to measure the two-site concurrence have been already implemented, thus our analysis can be tested in the laboratory. In order to make a closer contact with the experiment, we also computed a useful bound for the concurrence that can be more easily measured. In the relevant time-regime, this bound turns out to be very close to the actual value of the entanglement.

It is important to stress that all the results obtained in this work hold for averaged quantities. Single disorder realisations have very different aspects and the power-law decay itself of $C$ comes from single realisations of disorder in which $C_{i,j}$ is mostly zero, except for occasional “revivals”. It would be of great interest to analyse the full statistics of entanglement, something that is also experimentally accessible. In fact, it is possible that multifractal properties of the eigenstates in the MBL phase $24,61,62$ are reflected in full counting statistics of these revivals and higher moments of $C_{i,j}$.

A further perspective of future work would be to understand the power-law behaviour when the transition to the ergodic phase is approached. Other interesting questions concern the behaviour of the concurrence when a local quench is performed, especially in connection with the phenomenon of the logarithmic light-cone propagation of correlations $41$.

Note added. After the completion of this manuscript, we became aware of a related work $63$ discussing the dynamics of the two-site quantum mutual information in the MBL phase.

Quantum Information). We acknowledge the CINECA award under the ISCRA initiative, for the availability of high performance computing resources and support.

Appendix A: Phase diagram

Depending on the value of its coupling constants, the model studied in this work [Eq. (2)] presents three distinct phases: ergodic, MBL, and AL phases. Although several exact results\textsuperscript{10} on the ground state and the phase diagram along the non-interacting line\textsuperscript{46} are known, the location of the phase boundaries has not been worked out so far. A detailed analysis of the phase boundaries and of their properties lies beyond the purpose of the present work. Here we only need a reliable analysis that enables us to unambiguously choose the couplings in order to be in one of the three phases. Therefore, our aim is an (approximate) phase diagram for the Hamiltonian (2). We obtain it by combining different approaches. More precisely, we study: i) the time-dependence of the entanglement block-entropy for a bipartition of half the system size\textsuperscript{21–23}, and ii) the level-spacing statistics (LSS) of the Hamiltonian\textsuperscript{2}. A detailed discussion about the way these quantities can discriminate between the different phases can be found in the cited references.

The entanglement entropy \( S_A(t) \) of a block with \( A \) sites is defined as

\[
S_A = -\text{Tr}[\rho_A \log(\rho_A)],
\]

where \( \rho_A = \text{Tr}_{\neq A}[\rho] \) is the reduced state for the corresponding block sites. The increase in time of \( S_A(t) \) behaves differently in the three phases. We expect a ballistic growth in the ergodic phase, in contrast to a logarithmic dependence in the MBL phase and a saturation in the AL phase\textsuperscript{21–23}.

The rationale behind the spectral statistics approach\textsuperscript{2} lies on the fact that the LSS follows a Wigner-Dyson distribution in an ergodic system, and a Poisson law in an integrable system. As we have extensively discussed, MBL is a special case of integrable system (the reader can find more details on the spectral statistics in Refs. [4, 64–66]). In order to distinguish the various phases, instead of considering the whole LSS, we can restrict to a quantity whose average takes markedly different values on the two distributions. Having defined the gaps between adjacent many-body levels \( \{ E_n \} \) as \( \delta_n = E_{n+1} - E_n \geq 0 \), we define the ratio

\[
0 \leq r_n = \min\{\delta_n, \delta_{n+1}\}/\max\{\delta_n, \delta_{n+1}\} \leq 1.
\]  

(A2)

The different phases are characterised by a different value of the average \( \langle r_n \rangle \) over the level spacing distribution. From the results of Ref. [2], we expect to have \( \langle r_n \rangle \approx 0.386 \) in the localised phase (Poissonian LSS distribution), and \( \langle r_n \rangle \approx 0.5295 \) in the ergodic phase (Wigner-Dyson LSS distribution).

The colour code in Fig. 8 shows how this analysis can discriminate between the ergodic and the localised phase. In addition, for the points of the phase diagram marked by a symbol, we also studied the time-dependence of the entanglement entropy. Our analysis is too simplified to draw the phase boundary (it is not important for the present paper). We are however able to discriminate the three different phases in the selected points indicated by the symbols in Fig. 8. These values of the couplings have been used for the analysis of the two-site entanglement.

Appendix B: Weak interaction limit

In the regime in which the interaction \( V \) in Eq. (1) is finite but small, typically of the order of \( 10^{-2} - 10^{-1} \), we can clearly separate two different time scales. At the first one (\( t^* \), introduced in Sec. IV), the two-site entanglement saturates into a plateau, like in the AL phase. After the second one (defined by \( t_{\text{int}} \)), the power-law decay typical of the MBL phase begins. In this way we can set a clear distinction between AL and MBL regimes in the same time window. We expect the effect of MBL dynamics to appear at times of the order of \( t_{\text{int}} \approx 1/V \); for small interactions this scale can be much larger than the typical time scale associated to saturation in the AL phase: \( t_{\text{int}} \gg t^* \).

Our expectations are confirmed by the results shown in Fig. 9. As we can see in the top panel, for very small values of \( V \) the concurrence presents a “plateau” after the initial dynamics, where it is indistinguishable from the non-interacting case. Only after some finite time \( t_{\text{int}} \), the effects of interactions play a relevant role in the dynamics.
|C_V(0,0) − C_V=0(t)| as a function of time. The system has L = 24 sites, fixed disorder strength Δ = 3, and results are averaged over ~ 30 disorder realisations. The difference remains negligible up to a characteristic time t\text{int}, when interactions become relevant. Such time can be extrapolated by analysing when the curves start growing. (Bottom) Dependence of t\text{int} with V. The inset displays δt\text{int} ≡ t\text{int}(V,Δ) − t\text{int}(V ≫ 1,Δ), where t\text{int}(V ≫ 1,Δ) ≈ 0.7.

and the concurrence starts to decay. Since it is strictly related to the effect of interactions, we dub t\text{int} as the interaction time.

We can estimate t\text{int} by extracting it from the time evolution of the concurrence. To do that, we start giving a more quantitative definition of t\text{int}. To this end it is illuminating to plot, at fixed pseudo-disorder strength Δ, the difference |C_V(t) − C_V=0(t)| (Fig. 9, top panel). The interaction time t\text{int} is defined as the time at which the concurrence with V > 0 starts to differ from the non-interacting one (V = 0) more than a given threshold ε. We choose ε = 0.025, in such a way to capture the effect of the interactions, and not just small oscillations around the non interacting dynamics. The results however are qualitatively similar for slightly different values of ε.

The result of this analysis is reported in the bottom panel of Fig. 9. For the case shown in the figure, with disorder strength Δ = 3, such interaction time corresponds to t\text{int}(V) ∝ V^{-a} + b, with a ≈ 1.6 and b = 0.7 (see the inset). Therefore, our expectation of t\text{int} diverging as a power law for V → 0 is confirmed, but the power-law exponent is different from what we expected.

### Appendix C: Correlations in the ℓ-bit model

This appendix summarises the derivation of the time dependent spin-spin correlation functions in the effective ℓ-bit model (9): these correlations are necessary to determine the two-spin reduced density matrix and then the two-site entanglement (see also Ref. [27]). According to the ℓ-bit phenomenological model, the physical spin operators \{S_j^α\}_{j=1,...,L} of Hamiltonian (1) are, in principle, “locally” related to the ℓ-bit operators \{σ_m^{α,\prime}\}_{m=1,...,L} as

\[ \hat{S}_j^α = \sum_m \sum_{α'} \Delta_{j,m}^{α,α'} \hat{σ}_m^{α'} , \]

where \( \Delta_{j,m}^{α,α'} \) is localised, in the sense that it is non-vanishing only in a finite range around m. The precise form of \( \Delta_{j,m}^{α,α'} \) is generally non-trivial to obtain, but this is not important for us. The main message is that we expect the properties of the ℓ-bit operators and those of the physical spins to be similar. This is confirmed by the results shown in Sec. V: the concurrence obtained from the correlations of the ℓ-bit operators shows the same polynomial decay as the one numerically computed for the physical spins in Sec. IV. In this appendix we discuss in detail the computation of the dynamics of concurrence for pairs of ℓ-bit sites, that has been considered in Sec. V.

For such task we first need to compute the reduced density matrix \( ρ_{m,n}(t) \) for two different sites \( n \neq m \), which can be obtained from the correlations of its ℓ-bit operators

\[ ρ_{m,n}(t) = \sum_{a,α'=I,x,y,z} \langle \hat{σ}_{n}^α(t) \hat{σ}_{n}^{α'}(0) \rangle \hat{σ}_{m}^{α}(0) \hat{σ}_{m}^{α'}(0) . \]

It is important to stress that all the analytical formule we will find are valid for \( n \neq m \). Let us consider general initial uncorrelated states

\[ |ψ(0)⟩ = \otimes_{m=1}^L |χ_m(φ_m,θ_m)⟩ \]

\[ |χ_m(φ_m,θ_m)⟩ = \cos(φ_m) |↑⟩ + e^{iθ_m} \sin(φ_m) |↓⟩ , \]

where \( \{|↑⟩,|↓⟩\} \) are the eigenstates of the \( \hat{σ}_m^z \) operator. In this way, the correlators of any ℓ-bit operators can be easily handled: evaluating the expectations over the initial state, we find

\[ \langle \hat{σ}_m^{α,α'} \rangle = \langle \hat{σ}_m^α \rangle \langle \hat{σ}_m^{α'} \rangle , \]

due to the separability of this state. Exploiting this relation and using the Heisenberg representation, all the
correlators at any times can be analytically computed, as we will show below.

Since all the operators in the $\ell$-bit model commute, it is possible to analytically compute the time evolution of any operator in the Heisenberg picture. Since we will extensively use them in our analysis, let us just briefly recall the commutation relation between the Pauli matrices:

$$[\hat{\tau}^{\alpha}_{j}, \hat{\tau}^{\beta}_{j}] = 2i\epsilon_{\alpha\beta\gamma} \hat{\tau}^{\gamma}_{j},$$

$\epsilon_{\alpha\beta\gamma}$ being the Levi-Civita coefficient. The $\ell$-bit operators evolve in the Heisenberg picture as

$$\frac{d}{dt} \hat{\tau}^{\alpha}_{m} = i[H, \hat{\tau}^{\alpha}_{m}].$$

Since $\hat{\tau}^{z}_{m}$ commute with the Hamiltonian $\hat{H}$ of Eq. (9), they are time independent. Let us focus on the $\alpha \neq z$ cases. Applying the commutation relations in the Heisenberg equations, we obtain

$$\frac{d}{dt} \hat{\tau}^{\alpha}_{m} = \epsilon_{\alpha z} \hat{\tau}^{z}_{m} \hat{A}_{m}, \quad (C4)$$

with $\alpha = y(x)$ for $\alpha = x(y)$, and

$$\hat{A}_{m} = -2\left(h_{n}i + 2\sum_{j \neq m} J_{mn}^{\alpha} \hat{\tau}^{\alpha}_{j}\right).$$

The solution can be cast in the form

$$\hat{\tau}^{\alpha}_{m}(t) = \hat{C}^{\alpha}_{m} - e^{i\hat{A}_{m}t} + \hat{C}^{\alpha}_{m} + e^{-i\hat{A}_{m}t}, \quad (C5)$$

where

$$\hat{C}^{\alpha}_{m} = \frac{1}{2} \left[\hat{\tau}^{\alpha}_{m}(0) + i \epsilon_{\alpha z} \hat{\tau}^{z}_{m}(0)\right].$$

Given the above expressions, we can explicitly compute the expectation values for all local and two-point correlations. We will extensively use the following identity

$$e^{i\hat{A}_{m}t} = e^{-2ih_{m}1t} e^{-4iJ_{mn}^{\alpha} \hat{\tau}^{\alpha}_{m}t} \left(\prod_{j \neq m} e^{-4iJ_{mj}^{\alpha} \hat{\tau}^{\alpha}_{j}}\right), \quad (C6)$$

with $n$ being an arbitrary site index.

**Local averages.** For the $z$-spin terms we have

$$\langle \hat{\tau}^{z}_{m}(t) \rangle = \langle \tau^{z}_{m}(0) \rangle = \cos^{2}(\phi_{m}) - \sin^{2}(\phi_{m}). \quad (C7)$$

For the $x$-spin terms we obtain

$$\langle \hat{\tau}^{x}_{m}(t) \rangle = \sin(\phi_{m}) \cos(\phi_{m}) \left[e^{-i\theta} e^{-2ih_{m}t} K_{m,n}(t) + H.c.\right],$$

with $K_{m,n}(t) = \prod_{j \neq m} \left(e^{-4iJ_{nj}^{\alpha} t} \cos^{2}(\phi_{j}) + e^{4iJ_{nj}^{\alpha} t} \sin^{2}(\phi_{j})\right)$.

An analogous expression holds for the $y$-component.

**Two-point correlations.** For the $zz$-correlations we have

$$\langle \hat{\tau}^{z}_{m}(t) \hat{\tau}^{z}_{n}(t) \rangle = \langle \tau^{z}_{m}(0) \tau^{z}_{n}(0) \rangle = \langle \tau^{z}_{m}(0) \rangle \langle \tau^{z}_{n}(0) \rangle.$$

As for the $zx$-spin terms we obtain:

$$\langle \hat{\tau}^{z}_{m}(t) \hat{\tau}^{x}_{n}(t) \rangle = \langle \tau^{z}_{m}(0) \tau^{x}_{n}(0) \rangle = \langle \tau^{z}_{m}(0) \rangle \langle \tau^{x}_{n}(0) \rangle.$$

Finally we compute the last correlation terms $\langle \hat{\tau}^{\alpha}_{m}(t) \hat{\tau}^{\alpha'}_{n}(t) \rangle$ (with $\alpha, \alpha' = x, y$), which can be written as

$$\hat{\tau}^{\alpha}_{m}(t) = \sum_{b_{m}, b_{n} = -1, 1} \hat{X}^{(\alpha, b_{m})(\alpha', b_{n})}_{m,n}, \quad (C10)$$

with $\hat{X}^{(\alpha, b_{m})(\alpha', b_{n})}_{m,n} = \hat{C}^{\alpha}_{m} - b_{m} e^{i \hat{A}_{m}t} \hat{C}^{\alpha'}_{n} - b_{n} e^{i \hat{A}_{n}t}$

$$= \hat{C}^{\alpha}_{m} - b_{m} e^{-2i(b_{m}h_{n}1 + b_{n}2J_{mn}^{\alpha} \hat{\tau}^{\alpha}_{n})t} \hat{C}^{\alpha'}_{n} - b_{n} \left(\prod_{j \neq m,n} e^{-4i(b_{m}J_{mj}^{\alpha} + b_{n}J_{nj}^{\alpha}) \hat{\tau}^{\alpha}_{j}}\right)$$

The expectation value $\langle \hat{X}^{(\alpha, b_{m})(\alpha', b_{n})}_{m,n} \rangle$ is thus given by

$$\langle \hat{X}^{(\alpha, b_{m})(\alpha', b_{n})}_{m,n} \rangle = e^{-2i(b_{m}h_{n}1 + b_{n}2J_{mn}^{\alpha})t} G^{\alpha}_{t}(m, n, b_{m}, b_{n}) G^{\alpha'}_{t}(n, m, -b_{n}, -b_{m}) \ast F_{t}(m, n, b_{m}, b_{n}), \quad (C11)$$
where \[ F_t(m, n, b_m, b_n) = \prod_{j \neq m, n} \left[ e^{-4t(b_m J_{m,j} + b_n J_{n,j})} \cos^2(\phi_j) + e^{4t(b_m J_{m,j} + b_n J_{n,j})} \sin^2(\phi_j) \right] \]

and

\[ G_t^x(m, n, -1, b_n) = e^{4t b_n J_{n,m} t} e^{i\theta_m} \sin(\phi_m) \cos(\phi_m), \]
\[ G_t^x(m, n, +1, b_n) = e^{-4t b_n J_{n,m} t} e^{-i\theta_m} \sin(\phi_m) \cos(\phi_m), \]
\[ G_t^y(m, n, -1, b_n) = -i \langle \hat{C}_m^x e^{-4t b_n J_{n,m} \hat{\tau}_n^m t} \rangle, \]
\[ G_t^y(m, n, +1, b_n) = i \langle \hat{C}_m^x e^{-4t b_n J_{n,m} \hat{\tau}_n^m t} \rangle. \]

Using Eqs. (C10) and (C11), it is possible to compute \( \langle \hat{C}_m^{x,y}(t) \hat{C}_n^{x,y}(t) \rangle \).

**Appendix D: Finite-size corrections and errors due to statistical averages**

We first discuss the influence that finite-size effects may have during the relaxation dynamics of model (2).

Due to the presence of disorder, which is the responsible of many-body dephasing, we expect that deep in the localized phase the relaxation process will not be very sensitive to the size of the simulated systems, up to the time scales we are able to reach. This is what we observe in Fig. 10, when monitoring the time evolution of

![Figure 10](image)

**Figure 10.** Time evolution for the concurrence in the MBL phase (top panel, \( \Delta = 3, V = 1 \)) and in the ergodic phase (bottom panel, \( \Delta = 3, V = 1.5 \)). The various data sets are for different system sizes, according to the legend.

![Figure 11](image)

**Figure 11.** (Top) Relative variance of the concurrence as a function of time, as quantified by Eq. (D1). The data refer to three emblematic cases for \( \Delta = 3, \) in the ergodic phase \( (V = 1, 5), \) the MBL phase \( (V = 1), \) and very close to the AL phase \( (V = 0.01). \) (Bottom) Concurrence as a function of time, for the same cases as before. Error bars quantify the variance with respect to the disorder average. The results shown in the plots are averaged over 30 pseudo-disorder realizations.
the concurrence $C$. Finite-size effects in the MBL phase start to be visible for $L = 12$ sites at $t \gtrsim 10$, while they are virtually absent on the same time scale for $L \gtrsim 18$ (top panel). In the ergodic phase, due to the absence of localization, one would expect a more pronounced size dependence. Anyway in view of the very small time scales we are able to reach ($t \lesssim 10$), in all our simulations finite-size corrections are safely under control for $L \gtrsim 18$ (bottom panel). We point out that, in order to avoid any unwanted dependence on the matrix truncation of our MPS simulations, we fixed the bond order to avoid any unwanted dependence on the matrix.

We conclude this section by discussing the variance of our quantities of interest, which is induced by the average over different disorder realizations. Let us focus on the average concurrence defined in Eq. (7) and calculate its variance by propagating the error according to

$$\text{Var}(C(t)) = \sum_{i,j \in \text{bulk}} \left| \frac{\partial C(t)}{\partial C_{ij}} \right| \text{Var}(C_{ij}(t))$$

where $\text{Var}(C_{ij}(t))$ is the variance of the two-site concurrence. The data in Fig. 11 display three representative cases, where it emerges that the relative error induced by the pseudo-disorder averages (top panel) is decreasing with $V$. The averages have been performed over the same number of pseudo-disorder realizations as the data presented in Sec. IV. Apart from the quasi-AL phase (where we were however able to substantially increase the statistics, due to the integrability of the model), we notice that it also decreases with time, in such a way that our description for the concurrence long-time dynamics is basically unaffected (bottom panel). A similar result can be found for the imbalance $I$ of Eq. (8) (data not shown here).
