INTRODUCTION

Orchids are important ornamental plants characterised by their fantastic floral morphology and high levels of corolla-colour polymorphism and variability, which have played an important role in pollination and have excited biologists since Darwin (Gigord et al., 2001; Aguiar et al., 2020; Basist et al., 2021). As an important member of orchids, Cymbidium species are probably the earliest orchid, having been cultivated since before the time of Confucius (551–479 BC) for traditional use in worship and ornamentation (Chen and Tang, 1982; Du Puy et al., 2007). Currently, members of...
Anthocyanins, as a series of secondary metabolites, are water-soluble pigments that contribute colours from orange, pink, red, magenta, purple, blue, cyan to “black” (Hatier and Gould, 2007; Tanaka et al., 2008; Petroni and Tonelli, 2011; Moreau et al., 2012; Li et al., 2014). These pigments are an ideal model for genetics, molecular biology, and cell biology (Passeri et al., 2016). To date, hundreds of anthocyanins have been extensively studied and characterised, which were originally based on six common types of anthocyanidins (chromophores of anthocyanins), namely, petunidin, pelargonidin, delphinidin, cyanidin, malvidin, and peonidin. Accordingly, the synthetic route of anthocyanins and important related genes are well-studied and characterised in some model and non-model plants. Anthocyanins are derived from flavonoid biosynthetic pathways, and their biosynthesis has been divided into three stages (Grotewold, 2006). The first stage is phenylalanine and phenylpropanoid metabolism, which is shared among other secondary metabolisms. The second stage, flavonoid metabolism, is the crux of anthocyanin biosynthesis. Chalcone synthase (CHS) is the first key enzyme to produce chalcones, the precursor for all classes of flavonoids. Subsequently, an enzymatic reaction of chalcones to naringenins is catalysed by chalcone isomerase (CHI), which is followed by a conversion to dihydrokaempferol (DHK) by flavanone 3-hydroxylase (F3'H). The last step involves two participants, flavonoid 3'-hydroxylase (F3'H) and flavonoid 3', 5'-hydroxylase (F3' 5'H), corresponding to the respective products dihydroquercetin (DHQ) and dihydromyricetin (DHM). The final stage is anthocyanin metabolism, including two rate-limiting steps catalysed by dihydroflavonol reductase (DFR) and anthocyanidin synthase (ANS). Three kinds of products, delphinidin, pelargonidin, and cyanidin, undergo several modifications, such as glycosylation or methylation, by UDP-glucoside: flavonoid 3-O-glucosyltransferase (3GT) and anthocyanin methyltransferase (AMT).

Transgenic technology, expression, and suppression of the level of the anthocyanin synthetic gene have been verified as feasible to study the accumulation mechanism of anthocyanin in many plants. With the expression of UFGT, the skin colours of the Vitis and Litchi were turned red or violet from green (Ramazzotti et al., 2008; Zhao et al., 2012). Overexpression of SmANS from Salvia miltiorrhiza enhanced anthocyanin accumulation in the petals of S. miltiorrhiza f. alba and resulted in purple-red colour from white colour (Li et al., 2019). Using RNA interference (RNAi) technology to suppress CHS, ANS, and F3'/5'H, the petals of gentian plants exhibited pure white to pale-blue and magenta flowers accordingly (Nakatsuka et al., 2008). Consequently, using transgenic approaches to introduce exogenous anthocyanin genes into the targeted plant can obtain the desired coloration traits to produce new flower colour (Meyer et al., 1987; Katsumoto et al., 2007).

Cymbidium kanran is an ideal species to study coloration mechanisms because of numerous variations in floral coloration and abundant traditional varieties. In this study, we used purple-red flowers (with many purple-red pigments) and white flowers (greenish-white without purple-red pigments) as research materials (Figure 1). Through a combination of transcriptome sequencing, chemical, and molecular analysis, the mechanism of anthocyanin deficiency in white was preliminarily revealed. This dataset provided a novel resource to study and to understand the molecular mechanisms of coloration in C. kanran.

**MATERIALS AND METHODS**

**Plant Material and Freehand Sectioning**

White-type flowers and purple-red-type flowers of C. kanran were used as research materials in this study and cultivated in the greenhouse of Zhejiang Institute of Subtropical Crops in Wenzhou City, China (120°37’53”E, 28°08’8”N). For the first one, it has white flowers (Figure 1A), for the second, it has purple-red flowers with purple-red sepals/petals and white lip with purple-red spots (Figure 1B). The buds were about 2, 3 cm, 1–2 days before anthesis, and opened flowers were used for Real-Time PCR analysis. At the same time, about 3 cm length buds were selected for transcriptome sequencing and fully opened flowers were selected for freehand sectioning and pigment analysis. When harvested, all the materials were immediately frozen in liquid nitrogen (LN) and stored at −80°C except the freehand sectioning samples. Petals or lips of fully opened flowers were perpendicularly cut quickly to their longitudinal axis by hand sectioning with a new sharp double-edged razor blade. The sections were immersed in water and observed under an optical microscope.

**RNA Extraction, Library Construction, and RNA-seq**

The total RNA of each sample was isolated using TRIzol Reagent (Invitrogen Life Technologies, Carlsbad, CA, USA). Then, the integrity and concentration were checked on a 1% agarose gel and a NanoDrop ND-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA). The enriched mRNA was broken into short fragments, which were used to synthesise first- and second-strand cDNA. After that, the construction of the cDNA library was performed following the instructions of the manufacturer of the NEBNext Ultra RNA Library Prep Kit for Illumina (NEB, E7530, New England Biolabs, Ipswich, MA, USA) and NEBNext Multiplex Oligos for Illumina (NEB, E7500). Finally, the libraries of C. kanran buds were sequenced using an Illumina HiSeq™ 2500 by Biomarker Biotechnology Corporation (Beijing, China).

**RNA-seq Data Assembly, Annotation, and Differential Expression Analysis**

Raw data obtained by RNA-seq were primarily processed through in-house Perl scripts. In this step, clean reads were acquired
by removing reads containing adapters, reads containing poly-
N and low-quality reads from raw data. In addition, the 
Q20, Q30, GC content, and sequence duplication levels of 
the clean data were calculated to evaluate the sequencing 
quality. All the subsequent analyses were based on clean data 
with high quality. Transcriptome assembly was accomplished 
based on the fq file using Trinity software (https://github.com/
trinityrnaseq/trinityrnaseq/wiki) (Grabherr et al., 2011) with 
min_kmer_cov set to two by default and all other parameters set 
to default.

Gene function was annotated by BLASTX (Altschul et al., 
1997) program (http://www.ncbi.nlm.nih.gov/) based on 
the following databases: Nr (NCBI non redundant protein 
sequences); Nt (NCBI non-redundant nucleotide sequences); 
Pfam (Protein family); KOG/COG (Clusters of Orthologous 
Groups of proteins); Swiss-Prot (a manually annotated and 
reviewed protein sequence database); KO (KEGG Orthologue 
database); and GO (Gene Ontology).

Gene expression levels were estimated using RSEM software 
(http://deweylab.github.io/RSEM/) (Li and Dewey, 2011) for 
each sample. Differential expression analysis of the two 
samples was performed using DESeq (http://www.bioconductor. 
org/packages/3.8/bioc/html/DESeq.html). The resulting P-values 
were adjusted with the Benjamini-Hochberg method to control 
the false discovery rate. Genes with an adjusted $P < 0.05$ found 
by DESeq were identified as differentially expressed.

**Gene Validation and Expression Analysis**

Total RNA was isolated from *C. kanran* buds and flowers using 
the ZR Plant RNA MiniPrep Kit (Zymo Research, Irvine, CA, 
USA), and 1 µg RNA was used to synthesise oligo(dT)-primed 
first-strand cDNA by the QuantiTect Reverse Transcription
Zhou et al. Flower Coloration of Cymbidium kanran Kit (QIAGEN, Hilden, Germany) following the protocol of the manufacturer. The qRT-PCRs were performed in a 7300 Real-Time PCR System (Applied Biosystems, Foster Arthritis 5 City, CA, USA) using an SYBR premix Ex TaqTM Kit (TaKaRa, Kyoto, Japan). The reference gene we chose was actin (c114989.graph_c0). We calculated the relative expression level by the \(2^{-\Delta\Delta CT}\) method (Livak and Schmittgen, 2001).

**Measurement of Flower Flavonoids**

We used the relative quantitative method to analyze flavonoids from white and purple-red *C. kanran* opened flowers. Approximately 0.1 g (fresh weight) was extracted in 1 ml 70% methanol at 4°C for 1 day. After centrifugation for 5 min at 12,000 rpm, the supernatant was collected. Before analysis by high-performance liquid chromatography (HPLC), the extract was filtered to remove impurities. Samples were analysed using LC-ESI-QTRAP-MS/MS with an Agilent 1200 Series HPLC system (Agilent Technologies, Waldbronn, Germany) coupled to an Applied Biosystems 4000 QTRAP (Darmstadt, Germany), and quantification of flavonoids was carried out in MRM mode. The analytical conditions were as described previously (Chen et al., 2013). Data acquisition, peak integration, and calculations were performed using Analyst 1.5 software (AB Sciei, MA, USA). We quantified the anthocyanin and flavonol contents of white, purple-red, and intermediate phenotype *C. kanran* flowers for Pearson’s correlation coefficient in a different way. Approximately, 0.2 g (fresh weight) was extracted in 1 ml methanol: acetic acid: water (80:2:18, by vol.) at 4°C for 1 day. After centrifugation for 5 min at 12,000 rpm, the supernatant was collected, and the pellet was re-extracted for the second time. The combined supernatant was hydrolyzed in boiling water for 1 h and then quantitated to 2 ml. Before analysis by HPLC, the extract was filtered to remove impurities. HPLC was performed as previously described (Wang et al., 2014). Myricetin, kaempferol, quercetin,peonidin, malvidin, delphinidin, pelargonidin, and cyanidin (Sigma-Aldrich, China) were used for qualitative and quantitative analysis. Mean values and SDs were obtained from three replicates.

**Construction for Transient Expression by Particle Bombardment**

According to the gene transcript level and flavonoid content, *CkCHS-1*, *CkDFR*, and *CkANS* were screened as key genes encoding enzymes in the flavonoid metabolic pathway of *C. kanran*. Therefore, the three genes were divided into three groups, single genes, double genes, and triple genes, to be validated for transient expression by particle bombardment. The genes driven individually by the 35S promoter were cloned into the pCAMBIA1305.1 vector at the NcoI restriction site. The recombinant plasmid DNA was extracted and purified using an EndoFree Plasmid Giga Kit (QIAGEN, Hilden, Germany). Before bombardment, healthy white-type *C. kanran* flowers were collected, and the following procedure was conducted as described in the study by Ma et al. (2008).

![FIGURE 2](image-url) | Cross-sections of purple-red and white *C. kanran* showing the different colour patterns in petals and lips. Anatomic structure of purple-red *C. kanran* petals (A) and lips (C), white *C. kanran* petals (B), and lips (D). Scale bar = 500 μm.
RESULTS

Phenotypic Characterisation

In the process of domestication and cultivation of *C. kanran*, it is important to note the colour variety of the flowers. The most well-known cultivar, white-type *C. kanran*, has greenish-white petals and a white lip, both with greenish stripes (Figures 1A,C–G). Compared with white-type flowers, purple-red flowers exhibited purple-red petals with stripes of the same colour and a white lip with red spots and greenish stripes (Figures 1B,H–L). Because of the striking contrast in flower colour, white and purple-red *C. kanran* are the optimal candidates to reveal the flower coloration mechanism. To study the distribution of anthocyanin production in perianth cells, we analysed petal and lip cross-sections from white and purple-red *C. kanran* (Figure 2). In the petals, anthocyanins accumulated in the region from subepidermal cells to the xylem (Figure 2A), while in the lip, anthocyanins accumulated only in the epidermal cells of the adaxial surface (Figure 2C). However, white flowers showed no purple-red pigments (anthocyanins) in cells except chlorophyll (Figures 2B,D).

Flavonoid Content

Anthocyanins, as the largest group of water-soluble pigments, are responsible for most of the purple, blue, and red colours in the plants. In this study, we quantified the flavonoids of purple-red and white *C. kanran* flowers by a relative quantitative method. In purple-red flowers, only cyanidin, peonidin, and malvidin were present, and the cyanidin content was far greater than that of peonidin and malvidin. Delphinidin and pelargonidin-type anthocyanins were not detected, which probably was due to their extremely low content. Interestingly, the contents of myricetin (MY), kaempferol (KA), and quercetin (QU) in the white petals were lower than those in the purple-red *C. kanran* petals. However, it is worth noting that QU was detected in the white lip at a concentration two times higher than that in the purple-red lip, while the concentrations of MY and KA were similar in both study objects (Figure 3).

RNA-seq, Assembly, and Differential Expression Analysis

To illustrate the mechanism underlying the variation in flower coloration and to identify potential genes involved in this process, the petals and lips of purple-red and white *C. kanran* were used to generate four libraries for high-throughput sequencing. After quality checks, 61.90 Gb clean data were obtained, and the Q30 percentages (percentage of sequences with sequencing error rates <0.1%) of every sample were higher than 87.72%. These data showed that the sequencing quality and throughput were reliable enough to carry out further research. Short reads were then assembled into 181,335 transcripts and 74,713 unigenes by Trinity with mean lengths of 1,230 bp and 887 bp, respectively. After searching the reference sequences using BLASTX against KEGG, COG, KOG, GO, nr, and Swiss-Prot, we obtained a total of 26,930 unigenes providing a significant BLAST result.

Differentially expressed unigenes were grouped into 50 functional categories following KEGG annotation (Figure 4). The most prevalent functional category was photosynthesis, followed by phenylpropanoid metabolism, which was located upstream of flavonoid metabolism. Members involved in phenylalanine and flavonoid metabolism were also major parts of differentially expressed unigenes. These results indicated that the alternation of flavonoid metabolism was the underlying factor leading to a striking contrast in flower colour between purple-red and white *C. kanran*. Furthermore, the crucial genes taking part in three secondary metabolic pathways (phenylpropanoid, flavonoid, and anthocyanin metabolism referring to KEGG pathways) are listed in Table 1, consisting of 102 unigenes.

To compare levels of pigment biosynthesis-related gene expression, relative expression levels of “petals vs. lips of purple-red *C. kanran*,” “petals vs. lips of white *C. kanran*,” “petals of white *C. kanran* vs. petals of purple-red *C. kanran*,” and “lips of white *C. kanran* vs. lips of purple-red *C. kanran*” were conducted. Among the differences in the gene expression profile of white *C. kanran* vs. purple-red *C. kanran*, each one of cinnamate 4-hydroxylase (C4H), CHS, DFR, and ANS were downregulated, whereas each one of F 3’H, flavonol synthase (FLS), and CCoAOMT were upregulated. In the same flower, two C4H and each one of CHS, DFR, and ANS were upregulated but only one CHS was downregulated (petals vs. lips of purple-red *C. kanran*), however, there was only one CHS downregulated (petals vs. lips of white *C. kanran*) (Table 2).

Validating RNA-seq Data by qRT-PCR

To validate the RNA-seq expression profiles, seven differentially expressed unigenes encoding C4H, CHS, DFR, ANS, and FLS...

$^{c}$No. Down, the number of unigenes with lower expression level in the former than the latter.

were quantified by qRT-PCR (Figures 5A–U). The general expression profile obtained by qRT-PCR was perfectly consistent with that obtained by RNA-seq (Figure 5V), supporting the accuracy of the RNA-seq data.

CkC4H-3, CkCHS-1, CkDFR, and CkANS were highly expressed in purple-red floral tissues and expressed at low levels in white floral tissues (Figures 5A–I, M–R) Conversely, CkFLS was expressed at a higher level both in petals and the lip of white C. kanran than purple-red C. kanran (Figures 5S,T). Most of the anthocyanin-related genes exhibited higher expression levels in petals than in the lip, but the opposite results appeared in the CkCHS-2 expression pattern (Figures 5J–L). More interestingly, CkCHS-2 was abundantly expressed in white flowers but expressed at low levels in purple-red flowers (Figures 5J,K). Conversely, CkCHS-1 was highly expressed in purple-red flowers but had low expression levels in white flowers (Figures 5G,H), suggesting that white and purple-red flowers may have different CHSs to participate in the flavonoid/anthocyanin biosynthesis pathway. Additionally, CkDFR expression in three shades of purple-red flowers displayed a reverse trend to CkFLS (Figures 5W,X), which is in agreement with the competition to the same substrate between DFR and FLS.

Pearson's Correlation Coefficient Between Gene Transcript Level and Flavonoid Content

To uncover the relationship between gene expression and flavonoid content, the transcript abundance of flavonoid pathway genes and the accumulation of related products were detected in three shades of flowers (white, purple-red, and intermediate phenotype C. kanran). As presented in Figure 6,
Figure 5 | Transcript accumulation measurements of colour-related genes involved in the anthocyanidin metabolic process. (A–U) The qRT-PCR analysis of differentially expressed genes from RNA-Seq analysis. (V) Correlation of gene expression results obtained by qRT-PCR analysis and RNA-Seq for colour-related genes of the purple-red and white flower buds (length of approximately 3.0 cm). (W,X) Line charts of the relative expression levels of DFR and FLS in petals and lips, respectively. The Y-axis of all charts except V represents the relative expression level. Zhou et al. Flower Coloration of Cymbidium kanran

FIGURE 6 | Pearson’s correlation coefficient between gene transcript level (X-axis) and flavonoid content (Y-axis) in petals (A,C,E,G,I,K,M) and the lip (B,D,F,H,J,L,N) of C. kanran. Total flavonoids included MY, KA, QU, PEO, MA, and CY. The anthocyanidins of the DFR pathway included PEO, MA, and CY. The flavonol of the FLS pathway included MY, KA, and QU.

the concentration of flavonoids varied with the expression level of different genes. Normally, two variables show a strong correlation if the correlation coefficient \( r \) exceeds 0.6 in the Pearson correlation analysis. The contents of total flavonoids were significantly positively correlated with the expression levels of \( CkC4H-3 \) and \( CkCHS-1 \) in petals \((r^2 = 0.9055, r^2 = 0.4642)\) (Figures 6C,E). However, there was poor or no correlation between the total flavonoid content and \( CkC4H-1 \) and \( CkCHS-2 \) transcripts \((Figures 6AB,G,H)\), which agreed with the qRT-PCR results showing ruleless expression levels in purple-red and white C. kanran \((Figures 6A–C,J–L)\). \( CkDFR \) and \( CkANS \) were involved in the biosynthesis of CY, MA, and PEO and were positively correlated with the anthocyanidin content of the DFR pathway in petals \((Figures 6I,L)\).

Production of Purple-Red Pigmentation in White C. kanran by Transient Expression of CHS-1, DFR, and ANS Genes

According to Pearson’s correlation analysis in Figure 6, we conjectured that the recovery of the \( CkCHS-1, CkDFR, \) and \( CkANS \) genes in the white type could complete the anthocyanin pathway to display a red pigment similar to that of purple-red C. kanran. Hence, these three genes were divided into three groups, which are single genes, double genes, and triple genes, to be validated for transient expression by particle bombardment. Then, the three groups of genes were bombarded into white petals and lips. After incubation on 1/2 MS medium for 5 days, only the group of triple genes accumulated red spots in both petal and lip tissue \((Figure 7)\). This result supported that anthocyanin absence in white-type C. kanran probably resulted from the expression deficiency of \( CkCHS-1, CkDFR, \) and \( CkANS \). We further evaluated the temporal transcription of these three
The main pigments targeted for orchid flowers are anthocyanins that contribute to a variety of colours, such as red, purple, pink, and blue, while studies have shown that the main types of anthocyanidin aglycones in orchids are cyanidin, peonidin, and delphinidin (Liu et al., 2012; Vignolini et al., 2012; Wang et al., 2014; Liang et al., 2020; Zhang et al., 2020). In Oncidium Gower Ramsey, the red portion of petals contained a mixture of cyanidin-3-O-glucoside, delphinidin-3-O-glucoside, and peonidin-3-O-glucoside compounds (Liu et al., 2012). Flowers of Phalaenopsis with red-purple, purple-purple-violet, and violet to violet-blue colour were due to highly accumulated cyanidin-based anthocyanins, but no true-blue colour and no delphinidin was detected (Liang et al., 2020). In some cultivars of Cymbidium hybrids, only cyanidin-, malvidin-, and peonidin-type anthocyanins were identified (Woltering and Somhorst, 1990; Johnson et al., 1999). In C. kanran, the flavonoid composition exhibited a sharp shift between purple-red and white flowers. Three types (cyanidin, peonidin, and malvidin) of anthocyanidins were also detected in purple-red flowers but were absent in white flowers. While the transcript level of the colour-related gene showed that CkCHS-3, CkCHS-1, CkDFR, and CkANS were highly expressed corresponding to purple-red floral tissues compared with white-type floral tissues, but CkFLS had a higher level of expression in the white one, and a similar result was also achieved in Pleione limprichtii (Zhang et al., 2020). Dihydroflavonol reductase is a key enzyme in the biosynthesis of anthocyanins and can catalyze the reduction of three colourless dihydroflavonols, DHQ, DHK, and DHM, to leucoanthocyanidins. Because of the similar structure of the three substrates, it is easy to understand that DFRs from many species can utilise all three substrates (Heller et al., 1985; Meyer et al., 1987; Stich et al., 1992; Helariutta et al., 1993; Tanaka et al., 1995; Livak and Schmittgen, 2001; Ma et al., 2008; Chen et al., 2013). Dihydroflavonol reductases from some species specifically convert one or two types of dihydroflavonols. In Petunia and Cymbidium, pelargonidin-based brick red/orange flowers do not exist in nature because DFRs cloned from these two species cannot reduce DHK efficiently (Gerats et al., 1982; Forkmann and Ruhnau, 1987; Johnson et al., 1999), suggesting that DFRs have a striking substrate specificity (Springob et al., 2003). In Fragaria species, two DFRs were isolated, and one enzyme variant strongly preferred DHK as a substrate, whereas the other had a higher specificity for DHQ than for DHM (Miosic et al., 2014). Similar results were also reported in Ginkgo biloba and Freesia hybrida (Cheng et al., 2013; Li et al., 2017). In C. kanran, relative quantification showed that cyanidin, peonidin, and malvidin were detected, and the cyanidin content was far greater than that of peonidin and malvidin, indicating that the DFR isolated from C. kanran could catalyze DHQ conversion to leucoanthocyanin. However, more in vitro enzyme assays are needed to verify the substrate specificity of DFR with DHM and DHK.

Orchid flowers are striking for their specific patterns of colours in the perianths, and the regulation and formation of pigmentation is determined by specific cells of the different floral organs (Yu and Goh, 2001). In the case of C. kanran, the
distributions of anthocyanin production depended on the tissue specificity. The pigmentation in the petals showed anthocyanins concentrated in the outer layer of subepidermal cells to the xylem (Figure 2A), but in the lip, the red anthocyanins only accumulated in epidermal cells (Figure 2C). Orchid flowers have three petals, and one of the petals is morphologically different in structure and is known as the lip or labellum. However, the differences between the petals and lip were represented not only in shape but also in tissue and genes. The epidermal cells in the lip displayed different forms, in which the adaxial side cells were large and bubble-like, but the abaxial side cells were similar to the petal epidermal cells, which were small and flat. However, anthocyanins accumulated in the region from subepidermal cells to the xylem in the petal (Figure 2A), while in the lip, anthocyanins accumulated only in the epidermal cells of the adaxial surface (Figure 2C). Accordingly, pigments in the adaxial side of lips displayed bright-coloured pigmentation compared with those in petals (Figures 1J,K, 2A,C). Similar results were also reported in the leaves of Tipularia discolor orchid, the same anthocyanins in different anatomical locations led to a broad range of colours (Hughes et al., 2020). In addition, differentially expressed genes in transcriptome analysis of C. kanran supported that the molecular changes also existed between the lip and petals. In petals, CkCHS-1 was highly expressed, but CkCHS-2 was inversely expressed in the lip. In the Petunia hybrid, 12 genes encode CHS from a gene family, which were detected specifically in the margin of the corolla throughout all stages of flower development. Among them, CHS-A and CHS-J were expressed predominantly. These results indicated that CHS expression is regulated by different mechanisms in marginal picotee petals (Saito et al., 2006). According to a previous study, MADS-box genes might collectively regulate the genes involved in colour differentiation in petals and sepals during Cattleya orchid flower development, which may result in the spatiotemporal expression of anthocyanin biosynthesis pathway structural genes to determine colour differentiation (Li et al., 2020).

Knowledge of the molecular genetic basis of the flavonoid biosynthetic pathway allows us to improve the colour quality of plants. The simplest strategy to modify flower colour is to change the amounts of endogenous anthocyanins by regulating the essential enzymes required for flavonoid biosynthesis. For example, transgenic gentian plants with a suppressed ANS showed pale-blue-coloured flowers, while those with a suppressed CHS exhibited a more serious phenotype, i.e., pale-blue to pure white flowers (Nakatsuka et al., 2008). The manipulation of DFR and FLS, which are competing steps for flux towards anthocyanins and flavonols, led to an increase or decrease in anthocyanin content in the flower (Davies and Schwinn, 2010). In addition, the approach of regulating endogenous modification genes has also been utilised.

![FIGURE 9](Figure 9) Tentative pathways for (A) purple-red and white (B) C. kanran. CHS, chalcone synthase; CHI, chalcone isomerase; F3H, flavanone 3-hydroxylase; F3’H, flavonoid 3’-hydroxylase; F3’5’H, flavonoid 3’5’-hydroxylase; DFR, dihydroflavonol 4-reductase; ANR, anthocyanidin reductase; ANS, anthocyanidin synthase; FLS, flavonol synthase; LAR, leucoanthocyanidin reductase; UFGT, anthocyanidin 3-O-glucosyltransferase.)
in genetic engineering. For example, F3’5’H suppression by RNAi induced a flower colour change from purple to red in cyclamen (Boase et al., 2010). Similar transformations were also displayed in both F3’5’H and A5/3’AT (anthocyanin 5,3’-aromaticacyltransferase)-suppressed transgenic gentian plants (Nishihara and Nakatsuka, 2010). In C. kanran, the validation of the transient expression of key genes involved in colour formation showed that only triple genes, CkCHS-1, CkDFR, and CkANS could accumulate red spots in both the petal and lip tissue, indicating that the regulatory mechanism of coloration is complicated. To date, studies on some genetically defined genotypes or mutants revealing blocks of anthocyanin pathway gene expression have already been verified in many plants. In Forsythia, it was shown to be blocked in anthers at both the DFR and ANS levels but at the ANS level, only in petals (Rosati et al., 1999). However, the absence of anthocyanins in the skins of white berry varieties is due to a block only of UFGT expression in Vitis (Boss et al., 1996). Additionally, a point mutation of the CHS gene could result in the formation of the white flower of Matthiola incana (Hemleben et al., 2004). Another study in Oncidium also revealed that the failure of anthocyanin accumulation may be due to the inactivation of OgCHS caused by epigenetic methylation of the S’-upstream promoter regions (Liu et al., 2012). However, the silencing of three different CHS genes of the purple-colour flower of Dianthus chinensis via VIGS could obtain white or pale purple flower (Liu et al., 2021), suggesting that several CHS genes may be involved in the formation of coloration. In C. kanran, it is noteworthy that CkCHS-2 was abundantly expressed in white flowers but expressed at low levels in purple-red flowers (Figures 5J,K), and CkCHS-1 was highly expressed in purple-red flowers but had lower expression levels in white flowers (Figures 5G,H), indicating the complicated regulation of CHSs in C. kanran. Therefore, further studies need to be performed on the regulatory mechanism of anthocyanin pathway-related genes in C. kanran.

Thus, we tentatively speculated about the pathways for purple-red and white C. kanran (Figure 9). In purple-red C. kanran, flavonoids are initially derived from phenylalanine and phenylpropanoid metabolism. Subsequently, CkCHS is generated to produce chalcones, and CkCHI catalyzes chalcones into naringenin. Furthermore, naringenin can be converted through CkF3H, CkF3’H, and CkF3’5’H to produce dihydroxyflavonols including DHK, DHQ, and DHM. Following the above reaction, CkDFR and CkANS further catalyze the divergent conversion of dihydroflavonols to produce colourless cyanidin and delphinidin. In the end, CkUFGT and other GTs catalyze the glucosylation of anthocyanidins (peonidin, malvidin, and cyanidin), which were shown by HPLC analysis. A total of 102 candidate genes involved in the flower coloration of C. kanran were identified using transcriptome analysis. Gene expression profiles showed that four of these genes were positively correlated with anthocyanidin biosynthesis by qRT-PCR. Transient expression of CkCHS-1, CkDFR, and CkANS by particle bombardment results in the accumulation of anthocyanins in white flowers. These results indicated that CkCHS-1, CkDFR, and CkANS are the key genes involved in floral pigment accumulation in C. kanran. This study also provided a platform for C. kanran functional genomic research.

**CONCLUSIONS**

The white and purple-red phenotype C. kanran flowers had provided a unique experimental system to examine the mechanism for flower anthocyanin pigmentation. Compared with white flowers, purple-red flowers are comprised of three types of anthocyanin compounds, namely, peonidin, malvidin, and cyanidin, which were shown by HPLC analysis. A total of 102 candidate genes involved in the flower coloration of C. kanran were identified using transcriptome analysis. Gene expression profiles showed that four of these genes were positively correlated with anthocyanidin biosynthesis by qRT-PCR. Transient expression of CkCHS-1, CkDFR, and CkANS by particle bombardment results in the accumulation of anthocyanins in white flowers. These results indicated that CkCHS-1, CkDFR, and CkANS are the key genes involved in floral pigment accumulation in C. kanran. This study also provided a platform for C. kanran functional genomic research.

**DATA AVAILABILITY STATEMENT**

The datasets presented in this study can be found in online repositories. The name of the repository and accession number can be found below: National Centre for Biotechnology Information (NCBI) BioProject, https://www.ncbi.nlm.nih.gov/bioproject/, PRJNA744371.

**AUTHOR CONTRIBUTIONS**

ZZ, XW, and ZL designed the experiments. ZZ, XW, YY, and ZY performed all experiments. ZZ, XW, and ZW analysed the data. ZZ and XW wrote the manuscript. ZL revised the manuscript. All the authors have read and agreed to the published version of the manuscript.

**FUNDING**

This research was funded by the Natural Science Foundation of Zhejiang Province (grant nos. 12...
