Receptor endocytosis is a fundamental step in controlling the magnitude, duration, and nature of cell signaling events. Confluent endothelial cells are contact inhibited in their growth and respond poorly to the proliferative signals of vascular endothelial growth factor (VEGF). In a previous study, we found that the association of vascular endothelial cadherin (VEC) with VEGF receptor (VEGFR) type 2 contributes to density-dependent growth inhibition (Lampugnani, G.M., A. Zanetti, M. Corada, T. Takahashi, G. Balconi, F. Breviario, F. Orsenigo, A. Cattelino, R. Kemler, T.O. Daniel, and E. Dejana. 2003. J. Cell Biol. 161:793–804). In the present study, we describe the mechanism through which VEC reduces VEGFR-2 signaling. We found that VEGF induces the clathrin-dependent internalization of VEGFR-2. When VEC is absent or not engaged at junctions, VEGFR-2 is internalized more rapidly and remains in endosomal compartments for a longer time. Internalization does not terminate its signaling; instead, the internalized receptor is phosphorylated, codistributes with active phospholipase Cγ, and activates p44/42 mitogen-activated protein kinase phosphorylation and cell proliferation. Inhibition of VEGFR-2 internalization reestablishes the contact inhibition of cell growth, whereas silencing the junction-associated density-enhanced phosphatase-1/CD148 phosphatase restores VEGFR-2 internalization and signaling. Thus, VEC limits cell proliferation by retaining VEGFR-2 at the membrane and preventing its internalization into signaling compartments.

Introduction

Endothelial cells are contact inhibited in their growth and lose the capacity to respond to growth factors when they reach confluence. This phenomenon is mediated by different concurrent mechanisms. Molecules at cell to cell junctions, such as cadherins, may transfer signals that reduce the capacity of the cells to respond to proliferative stimuli (Dejana, 2004; Gumbiner, 2005). Cadherins are located at intercellular adherens junctions and are linked to different intracellular partners that include β-catenin, plakoglobin, p120, Src (Gumbiner, 2005), csk (Baumeister et al., 2005), and density-enhanced phosphatase-1 (DEP-1)/CD148. β-catenin, plakoglobin, and p120 can also translocate to the nucleus and modulate cell transcription. In tumor cells, the negative effect of epithelial cadherin (E-cadherin) on cell growth is a result of its capacity to bind β-catenin and inhibit its translocation to the nucleus. This effect is detected in tumor cell lines in which cytosolic β-catenin ubiquitination and destruction is impaired (St Croix et al., 1998; Mueller et al., 2000; Gottardi et al., 2001; Stockinger et al., 2001; Bryant and Stow, 2005).

Endothelial cells express a cell-specific cadherin called vascular endothelial cadherin (VEC). This protein exerts a negative effect on cell growth by binding VEGF receptor (VEGFR) type 2 and inhibiting its signaling activity (Carmeliet et al., 1999; Shay-Salit et al., 2002; Lampugnani et al., 2003; Dejana, 2004). VEGF is a major growth factor for endothelial cells and plays an important role in the formation of new vessels during embryogenesis and in proliferative diseases (Alitalo et al., 2005; Carmeliet, 2005; Ferrara and Kerbel, 2005). In blood endothelium, the activities of VEGF are mediated by its...
interaction with two tyrosine kinase receptors, VEGFR-1 (flt-1) and -2 (flk/KDR), as well as neuropilins. The growth signals are transferred, to a large extent, through the activation of PLC-γ, PKC, and subsequently p44/42 MAPK (Takahashi et al., 1999, 2001; Matsumoto et al., 2005; Singh et al., 2005).

We found that in contact-inhibited endothelial cells, VEGFR-2 forms a complex with VEC that results in the inhibition of its tyrosine phosphorylation and, consequently, in the attenuation of MAPK activation. This effect was attributed to the phosphatase DEP-1/CD148 that, by binding β-catenin and p120, may associate with the cadherin–receptor complex and dephosphorylate the receptor (Lampugnani et al., 2003). In this study, we go further by describing another aspect of this phenomenon.

Upon activation with specific ligands, growth factor receptors are internalized via clathrin-dependent and -independent pathways. In many cases, this process leads to signaling termination via degradation of the activated receptor complex. Therefore, internalization is considered an important mechanism through which cells may control the intensity and duration of signal transduction.

However, more recent findings indicate that internalization is not just a sink through which receptors are degraded (Di Fiore and De Camilli, 2001; Miaczynska et al., 2004). On the contrary, some receptors, such as TGF-β, EGF, or NGF receptors, can maintain their signaling activity from within intracellular compartments (Suyama et al., 2002; Di Guglielmo et al., 2003; Bryant et al., 2005; Sigismund et al., 2005).

Little is known about the internalization pathways followed by VEGFR-2 or their functional significance (Labrecque et al., 2003; Bhattacharya et al., 2005; Mitola et al., 2006). It has been reported that cadherins may influence growth factor receptor internalization, but the extent to which they do depends on the cadherin or growth factor receptor. In tumor cell lines, N-cadherin forms a complex with FGF receptor 1 that inhibits its internalization and degradation. This causes a sustained FGF signaling and abnormal cell growth (Suyama et al., 2002). In contrast, E-cadherin internalizes with FGF receptor 1, which facilitates its nuclear translocation and signaling activity (Bryant and Stow, 2005; Bryant et al., 2005).

In this study, we analyzed the role of VEC on VEGFR-2 internalization and signaling in endothelial cells. We found that the receptor is internalized more rapidly and efficiently when VEC is absent or not clustered at intercellular contacts. Strikingly, internalization does not terminate receptor signaling, which instead continues in endosomes. This may explain why VEC-null cells present increased and uncontrolled growth.

Results

VEC expression inhibits VEGFR-2 internalization

We first investigated whether the establishment of cell to cell contact modulates VEGFR-2 internalization. Using freshly
isolated human umbilical vein endothelial cells (HUVECs) stimulated with VEGF, we observed that VEGFR-2 endocytosis, which was evaluated by immunofluorescence labeling of intracellular vesicular compartments, was significantly reduced by cell density (Fig. 1 A). Time course analysis revealed that in sparse cells, the number of receptor-positive vesicles increased more rapidly and to a larger extent than in confluent cells (Fig. 1 A, bottom).

This first observation suggested that the establishment of cell to cell contact reduced VEGFR-2 internalization. Because VEC plays a role in VEGFR-2 signaling, we investigated whether VEC could be involved in VEGFR-2 internalization. We compared syngenic endothelial cell lines differing for the expression of VEC. These cells had been characterized previously in detail and presented superimposable levels of VEGFR-2 (see Fig. 8; Lampugnani et al., 2002, 2003). As shown in Fig. 1 B, after the addition of VEGF, the number of VEGFR-2-containing vesicular compartments is markedly higher in the absence of VEC. Quantification of the amount of biotinylated receptor that was internalized, degraded, or recycled back to the plasma membrane is reported in Fig. 2. In VEC-null endothelium, the receptor is internalized more quickly and to a higher extent than in VEC-positive cells (Fig. 2, A and B).

In VEC-null cells, receptor internalization kinetics appear faster in biotinylation than in immunofluorescence experiments. This apparent discrepancy may be caused by internalization compartments, which can be measured in biotinylation experiments because they are protected from glutathione (GSH) reduction but are not yet clustered in structures resolvable in immunofluorescence microscopy.

The overall amount of internalized receptor for the duration of the experiment is about fourfold more in VEC-null than -positive cells. Receptor degradation exceeds recycling by about fivefold in both cell types, but both parameters are significantly increased in the absence of VEC (Fig. 2, C and D). These data indicate that a higher amount of VEGFR-2 is internalized, degraded, and recycled in the absence of VEC.

Internalization of growth factor receptors may follow clathrin-dependent or -independent pathways. Among the latter, caveolae have been shown to regulate receptor internalization directed toward degradation (Di Guglielmo et al., 2003; Sigismund et al., 2005). Our codistribution experiments of VEGFR-2 with early endosomal antigen-1 (EEA-1) and caveolin-1 show that VEGFR-2 internalizes mostly in EEA-1–positive early endosomes (Fig. 3) and to a very low extent in caveolae. Colocalization of VEGFR-2 and the caveolar component PV-1 (Stan et al., 2004; Stan, 2005) was also negligible (unpublished data). To control whether caveolae were expressed correctly and to a comparable extent in both VEC-null and -positive cells, we costained these structures with PV-1 and caveolin antibodies. As shown in Fig. S1 (available at http://www.jcb.org/cgi/content/full/jcb.200602080/DC1), the extensive and comparable colocalization of caveolin and PV-1 could be observed in both cell types, suggesting structural integrity of the caveolar compartment.

The preferential distribution of VEGFR-2 in EEA-1–positive endosomes was further confirmed using immuno-EM (Fig. 3 C). In addition, silencing clathrin heavy chain expression either by siRNA (see Fig. 8 and Fig. S3, available at http://www.jcb.org/cgi/content/full/jcb.200602080/DC1) or disrupting clathrin-coated pits by hypertonic medium blocked receptor internalization both in VEC-positive and -null cells (Fig. 4). In contrast, after incubation with filipin at a concentration able to fully disrupt lipid rafts and caveolae (Schnitzer et al., 1994;
Andriopoulou et al., 1999), receptor internalization did not significantly change (Fig. 4).

We also performed experiments at different time points (5, 7, 10, 20, and 30 min) after the addition of VEGF in VEC-null and -positive cells using caveolin and PV-1 as markers of caveolae and EEA-1 and Rab-5 as markers of early endosomes. At all time points considered, we could not see internalized VEGFR-2 in vesicles positive to either caveolin or PV-1 but only in bona fide early endosomes (unpublished data). These data strongly suggest that, at least within the experimental conditions used, VEGFR-2 endocytosis in endothelial cells is mostly clathrin dependent.

**Internalized VEGFR-2 retains signaling activity**

In the absence of VEC, endothelial cells respond more effectively to growth signals transferred by VEGFR-2. From the aforementioned observations, we concluded that VEGFR-2 is internalized more quickly and to a larger extent in VEC-null cells than in VEC-positive cells. Therefore, we asked whether the receptor retains its signaling activity when sequestered in intracellular compartments.

Figure 3. Internalized VEGFR-2 colocalizes with EEA-1-positive compartments by immunofluorescence analysis. HUVECs, VEC-null, and VEC-positive cells were double labeled for VEGFR-2 and either EEA-1 or caveolin-1. Cells were activated with VEGF for 10 min. (A) Representative examples of confocal images for each antigen and their respective merges (boxed areas; 3.5-fold magnification) are shown for confluent HUVECs after treatment with VEGF. VEGFR-2 was revealed with an AlexaFluor488-conjugated secondary antibody and is shown in green. EEA-1 and caveolin revealed with AlexaFluor647-conjugated secondary antibodies are shown in red. Nuclei appear blue after DAPI staining. Bars, 10 μm. (B) To quantify colocalization events, images were analyzed using the ImageJ colocalization plugin (as described in Materials and methods). The graphs present the number of colocalization events normalized for the number of VEGFR-2-positive compartments. After VEGF treatment, ~45–55% of VEGFR-2-positive compartments showed colocalization with EEA-1 in all of the situations examined. Colocalization of internalized VEGFR-2 with caveolin-1 was negligible. Values are the mean of at least three experiments ± SD (error bars). In each experiment, at least five random fields were analyzed for each point. * P ≤ 0.01 by t test. (C, a and b) Immunogold labeling of EEA-1 (10 nm gold; arrows) and VEGFR-2 (15 nm gold; arrowheads) on an ultrathin cryosection of VEG-null and -positive cells treated with VEGF for 10 min. The panels display VEGFR-2 labeling of EEA-1-positive endosomes in VEC-null rather than in VEC-positive cells. (c and d) Under the same conditions, morphologically identified caveolae are devoid of VEGFR-2. Bar (a), 227 nm; (b) 222 nm; (c) 350 nm; (d) 370 nm.

We first tested whether the internalized receptor retained tyrosine phosphorylation by cell fractionation on an iodixanol gradient (Yeaman et al., 2001). Antibodies recognizing phosphotyrosine (PY) 1214- and PY1054/59–VEGFR-2 were used. As shown in Fig. 5, in the absence of VEC, a higher amount of phosphorylated VEGFR-2 is detected in intracellular fractions, whereas in the presence of VEC, the phosphorylated receptor remains preferentially in fractions corresponding to peripheral plasma membranes.

Phosphorylation of VEGFR-2 tyrosine 1175 is required for binding and activation of PLC-γ, which is the major effector of VEGF-mediated cell proliferation (Takahashi et al., 2001). By using antibodies specific for PY1175–VEGFR-2, we observed that in the absence of VEC, a higher amount of phosphorylated VEGFR-2 is detected in intracellular fractions, whereas in the presence of VEC, the phosphorylated receptor remains preferentially in fractions corresponding to peripheral plasma membranes.
Inhibition of VEGFR-2 internalization affects its proliferative signaling

Overall, the aforementioned data indicate that VEC limits receptor activation and internalization. In the absence of this protein, the receptor is internalized more efficiently and retains its active state for a longer time, leading to continuous proliferative signaling.

To further test this hypothesis, we prevented receptor internalization by silencing clathrin with two specific siRNAs.
domains of VEC involved in this process (Lampugnani et al., 2003). We then investigated the mechanism through which VEC inhibits VEGFR-2 internalization. In a previous study, we found that VEC forms a complex with VEGFR-2, and we analyzed the mechanisms through which VEC association with VEGFR-2 internalization protects the receptor from dephosphorylation (unpublished data). Overall, these results strongly suggest that receptor internalization is a consequence of binding to VEC.

Figure 6. **Internalized VEGFR-2 is phosphorylated at tyrosine 1175.** (A) VEC-null and -positive cells were stimulated with VEGF as in Fig. 1, fixed, and processed for immunofluorescence microscopy. The vesicular labeling pattern observed with PY1175-VEGFR2 antibody after stimulation with VEGF was significantly more abundant in VEC-null than in VEC-positive cells. Nuclei appear blue after DAPI staining. Bar, 20 μm. (B) Images were analyzed by ImageJ to quantify PY1175-VEGFR2-positive compartments (see Materials and methods). The graph presents the mean ± SD (error bars) calculated from 18 random fields that were analyzed through ImageJ in five independent experiments and is normalized to the number of cells per field. In each experiment, at least three random fields were analyzed. *P ≤ 0.01 comparing VEC-null with -positive cells after VEGF by analysis of variance and the Duncan test.

(Figs. 4, 8, and S3) that target independent sequences of clathrin heavy chain messenger. As expected, VEGF-induced phosphorylation of VEGFR-2 and activation of p44/42 MAPK were higher in the absence than in the presence of VEC (Fig. 8). When siRNA clathrin was applied to VEC-null cells, both receptor and MAPK phosphorylation dropped to values comparable with those of VEC-positive cells. In contrast, in the presence of VEC, the effect of siRNA clathrin was either weak or undetectable. Consistently, the inhibition of MAPK activation was also observed by treating the cells with hypertonic medium, whereas treatment with filipin did not modify MAPK activation in response to VEGF either in VEC-positive or -null cells (unpublished data). Overall, these results strongly suggest that internalization protects the receptor from dephosphorylation and, therefore, increases and prolongs its proliferative signaling.

**VEC association with VEGFR-2 is required for receptor retention at the plasma membrane**

We then investigated the mechanism through which VEC inhibits VEGFR-2 internalization. In a previous study, we found that VEC forms a complex with VEGFR-2, and we analyzed the domains of VEC involved in this process (Lampugnani et al., 2003). VEC mutants lacking either the β-catenin– or p120-binding domains were unable or less efficient, respectively, to communoprecipitate VEGFR-2. We found that these mutants were also unable to significantly prevent VEGFR-2 internalization (Fig. S4, available at http://www.jcb.org/cgi/content/full/jcb.200602080/DC1), suggesting that receptor internalization is reduced as a consequence of binding to VEC.

Similar to E-cadherin (for review see Bryant and Stow, 2004), VEC can be internalized through clathrin-coated pits (Xiao et al., 2005). We tested whether VEC codistributes with VEGFR-2 in intracellular compartments. As reported in Fig. 9 upon VEGF activation, no significant codistribution of VEC with VEGFR-2–positive vesicles is detected in VEC-positive cells and HUVECs (Fig. S4). Only junctional colocalization can be observed (Fig. 9). The lack of codistribution in internal compartments was confirmed by immuno-EM (unpublished data). Collectively, these data suggest that the receptor internalizes upon dissociation from VEC.

**VEGFR-2 phosphorylation is required for internalization and signaling**

In previous studies, we showed that the phosphatase DEP-1/CD148 can reduce VEGFR-2 signaling. DEP-1/CD148 can associate with β-catenin and p120 (Holsinger et al., 2002; Palka et al., 2003) and with the VEC–VEGFR-2 complex, reducing VEGFR-2 phosphorylation (Lampugnani et al., 2003). Therefore, we tested whether DEP-1/CD148 could also reduce receptor internalization.

As reported in Fig. 10 A, in endothelial cells transfected with DEP-1/CD148 siRNA, VEGFR-2 internalization is significantly higher. This effect is accompanied by an increase in VEGFR-2 phosphorylation and MAPK activation (Lampugnani et al., 2003). These data suggest that retention of VEGFR-2 at the membrane by VEC allows its dephosphorylation by DEP-1/CD148 and limits its internalization and signaling.

**Discussion**

In this study, we report a novel aspect of the mechanism through which VEC expression and clustering inhibits VEGFR-2 proliferative signaling. We found that in the absence of VEC or in conditions in which VEC is not clustered at adherens junctions as in sparse cells, VEGFR-2 is endocytosed to a higher extent in intracellular compartments, from where it maintains its signaling activity. VEC could therefore reduce receptor activity by inhibiting VEGFR-2 internalization and promoting its inactivation at the cell surface.

In our experimental conditions, VEGFR-2 is internalized in early endosomes mostly through a clathrin-dependent pathway. We were unable to detect caveolin-1–positive vesicles containing VEGFR-2, and we could not inhibit receptor internalization using a caveolea-perturbing drug such as filipin (Schnitzer et al., 1994; Andriopoulou et al., 1999). Other studies found the codistribution of VEGFR-2 with caveolin-1 (Labrecque et al., 2003; Bhattacharya et al., 2005; Ikeda et al., 2005), and we cannot exclude that under different experimental conditions, VEGFR-2 may be internalized through caveolea.
However, the observed association with caveolin-1 may also represent a mechanism of receptor compartmentalization at the plasma membrane. It was found that caveolin-1 would form a molecular complex with VEGFR-2 that inhibits receptor activation in resting cells. Upon activation of the cells with VEGF, caveolin-1 is phosphorylated, and the complex rapidly dissociates (Labrecque et al., 2003). Thus, it is tempting to speculate that similar to TGF-β receptor (Di Guglielmo et al., 2003), once VEGFR-2 is released from the caveolin-1 complex, it becomes available for internalization in clathrin-coated pits. In agreement with this model, the overexpression of caveolin-1 in transgenic mice reduces permeability and angiogenic response to VEGF (Bauer et al., 2005).

It has been reported that VEGFR-2 internalization and degradation are regulated by ubiquitination through a Cbl-dependent mechanism (Duval et al., 2003) or C-tail serine phosphorylation by activated PKC (Singh et al., 2005). These mechanisms may coexist and may be responsible for the amount of receptor degradation reported here.

Our observations support the hypothesis that internalized VEGFR-2 maintains its activity. These data are in agreement with recent publications indicating that signaling through

Figure 7. Colocalization of internalized VEGFR-2 and activated PLC-γ. (A) VEC-null and -positive cells were labeled in vivo with antibodies to VEGFR-2, stimulated with VEGF as in Fig. 6, acid washed, fixed, and processed for immunofluorescence microscopy. Cells were double labeled with an antibody that recognizes PLC-γ only when phosphorylated at tyrosine 783. VEGFR-2 was revealed with an AlexaFluor488-conjugated secondary antibody and is shown in green. PY783–PLC-γ, which was revealed with an AlexaFluor647-conjugated secondary antibody, is shown in red. For each cell type, the bottom panel on the right (threefold magnification of the boxed areas) shows the colocalization of VEGFR-2 and PY783–PLC-γ (pink) set upon the VEGFR-2 background (gray). This was obtained through the ImageJ colocalization plugin (see Materials and methods for details). Arrows point to the colocalization of PY783–PLC-γ and VEGFR-2. Bars, 10 μm. (B) The confocal images were analyzed through ImageJ to calculate the number of colocalization events. These values, which were normalized over the number of VEGFR-2-positive compartments per cell, are presented in the graph. After VEGF treatment, colocalization was about fivefold higher in VEC-null than in VEC-positive cells. Values in the graph are the mean from three independent experiments ± SD (error bars). In each experiment, each point was calculated from at least five random fields. *, P ≤ 0.01 comparing VEC-null with -positive cells after VEGF by analysis of variance and the Duncan test.

Figure 8. Silencing clathrin expression inhibits VEGFR-2 phosphorylation and signaling in VEC-null cells. VEC-null and -positive cells were transfected with Stealth siRNA-targeting mouse clathrin heavy chain. Two oligonucleotides (a and b; respective sequences are reported in Materials and methods) were used that target two independent sequences of the clathrin heavy chain mRNA. Negative Stealth siRNA duplex was used as a control. After 72 h, cells were treated with VEGF or control medium for 10 min. They were then extracted and processed for Western blotting. Clathrin siRNA reduced clathrin heavy chain levels by ~75% (oligonucleotide a) and 90% (oligonucleotide b) in both cell types. VEGFR-2 phosphorylation at tyrosine 1214 and p44/42 MAPK phosphorylation in response to VEGF were strongly inhibited in VEC-null cells, whereas these parameters were only barely affected in VEC-positive cells. Comparable results were obtained for PY1054/59–VEGFR-2 (not depicted). The graphs show the quantification of these effects as means ± SD (error bars) of five independent experiments. Fold increase after VEGF is shown for PY1214–VEGFR-2 and phospho-p44/42 MAPK. * , P ≤ 0.01 versus negative siRNA by variant analysis and the Dunnet test.
growth factor receptors does not occur only at the cell membrane but may continue even more effectively from intracellular compartments (Di Fiore and De Camilli, 2001; Sorkin and Von Zastrow, 2002; Miaczynska et al., 2004; Le Roy and Wrana, 2005). Clathrin-dependent internalization of TGF-β in early endosomes, where the Smad2 anchor SARA is enriched, promotes TGF-β signaling (Di Guglielmo et al., 2003). EGF receptor is internalized shortly after ligand addition in intracellular compartments together with its downstream signaling factors such as, Grb2, and mSOS (Di Guglielmo et al., 1994) and maintains its signaling activity (Pennaock and Wang, 2003). Similarly, the specific activation of endosome-associated PDGF receptor leads to the activation of its major signaling pathways (Wang et al., 2004). Thus, as for VEGFR-2, endocytic transport is important not only for receptor turnover but also for regulating signal transduction and for mediating the formation of specialized signaling complexes.

A novel aspect of our work is that VEC inhibits VEGFR-2 internalization, thereby reducing its cell growth signaling activity. How can VEC inhibit receptor endocytosis? A likely hypothesis is that VEC retains VEGFR-2 at the membrane by binding to it. In addition to our studies, others have reported (Shay-Salit et al., 2002; Lampugnani et al., 2003; Weis et al., 2004; Lambeng et al., 2005) that VEGFR-2 couples with VEC. This process requires the binding of VEC to β-catenin and, to a lesser extent, to p120. In the present study, we found that mutants of VEC lacking the cytoplasmic domain responsible for binding either β-catenin or p120 and unable to associate with VEGFR-2 (Lampugnani et al., 2003) do not prevent VEGFR-2 internalization. This supports the idea that VEC–VEGFR-2 coupling is required to inhibit receptor endocytosis.

Cadherins themselves are endocytosed via several different routes, including clathrin-dependent (Le et al., 1999; Palacios et al., 2002; Ivanov et al., 2004; Izumi et al., 2004) and -independent pathways (Akhtar and Hotchin, 2001; Paterson et al., 2003). Therefore, cotrafficking of receptor and cadherin complexes is possible (for reviews see Bryant and Stow, 2004, 2005; Cavallaro and Christofori, 2004). However, under our experimental conditions, we could detect VEC in intracellular compartments (Xiao et al., 2005), but we could not see codistribution with the receptor. Thus, it is likely that the receptor dissociates from VEC before internalization (Fig. 9).

In a previous study, the phosphatase DEP-1/CD148 was found to play a role in the inhibitory effect of VEC on VEGFR-2 signaling (Lampugnani et al., 2003). This phosphatase associates with VEC through its binding to β-catenin and p120 and, in this way, reduces VEGFR-2 phosphorylation (Lampugnani et al., 2003). We report that DEP-1/CD148 could prevent VEGFR-2 internalization along with the reduction of receptor phosphorylation and signaling. Therefore, it is possible that VEC, by retaining VEGFR-2 at the cell surface, allows its dephosphorylation by DEP-1/CD148, which, in turn, inhibits its internalization and signaling.

Besides VEC, VEGFR-2 was found to bind to integrins (Soldi et al., 1999). Another study reported that when cells are plated on collagen I, the phosphatase SHP2 can associate with VEGFR-2 and stimulate its internalization. SHP2 activates Src, which in turn activates dynamin II–dependent receptor internalization (Mitola et al., 2006). Interestingly, this phenomenon does not occur when cells are plated on vitronectin, and SHP2 does not

**Figure 9.** VEC does not codistribute with VEGFR-2 in internal compartments. VEC-positive cells were treated with VEGF for 10 min, double stained for VEGF2 and VEC, and analyzed by confocal microscopy. Besides junctional staining, VEC did not show any obvious vesicular pattern. VEGF2 and VEC appeared to codistribute only at cell–cell contacts and not in intracellular compartments. The bottom panel on the right (2.6-fold magnification of the boxed areas) shows the colocalization of VEGF2 and VEC (yellow) set upon the VEC background (gray). This was obtained through the colocalization plugin of ImageJ (see Materials and methods for details). Arrows point to the junctional colocalization of VEGF2 and VEC. Bars, 10 μm.

**Figure 10.** DEP-1/CD148 silencing in VEC-positive cells increases internalization, tyrosine phosphorylation, and activity of VEGFR-2. VEC-positive cells were transfected with either Stealth siRNA-targeting mouse DEP-1/CD148 or a negative Stealth siRNA control duplex. After 72 h, cells were treated with VEGF for 10 min and either fixed and processed for immunofluorescence microscopy or extracted and processed for Western blotting. DEP-1/CD148 siRNA reduced DEP-1/CD148 protein by ~45% (A). (A) VEGFR-2-positive vesicular compartments were found to be significantly higher (>80%) in VEGF-treated cells after transfection with DEP-1/CD148 siRNA. Means of three independent experiments ± SD (error bars) are shown. In each experiment, at least five random fields were analyzed. *, P ≤ 0.01 comparing negative with DEP-1 siRNA interference by analysis of variance and the Duncan test. (B) Phosphorylation of VEGFR-2 at tyrosine 1214 and of p44/42 MAPK was increased by ~80 and 60%, respectively, after DEP-1/CD148 siRNA transfection in VEGF-treated cells.
bind to VEGFR-2 (Mitola et al., 2006). These observations suggest that the capacity of different adhesive proteins to complex with growth factor receptors and modulate their internalization and signaling may be a general paradigm. In this way, cells may modulate their growth and survival as a function of density and interaction with specific matrix proteins.

In conclusion, the results reported in this study are consistent with the idea that VEGFR-2 proliferative signaling is increased by endocytosis. The inhibitory role of VEC is likely that of binding and retaining the receptor at the cell surface, preventing its endocytosis, and favoring inactivation by DEP-1/CD148. Stealth oligonucleotides were used as follows: a, 5′-GCAUUGUUGUUCAUAACCUUUA-3′ (start nucleotide was 2,118 bases downstream of the start codon); b, 5′-GAAGAACCUCUUGCGCCGAUAUA-3′ (start nucleotide was 1,284 bases downstream of the start codon) to target mouse clathrin heavy chain; and c, 5′-UCGACCCGACAGCAUGUUGGAAA-3′. Start nucleotide was at 4,023 bases downstream of the start codon to target mouse DEP-1/CD148. As a control, a Stealth siRNA-negative control duplex oligonucleotide (Invitrogen) with a C/G content equivalent to the positive oligonucleotide was used.

Materials and methods

Primary antibodies

For the detection of VEGFR-2, anti-human VEGFR-2 (single chain recombinant; clone scFvA7 with E tag; RDI and Fitzgerald) and anti-mouse VEGFR-2 (rat clone Avas121; RDI and Fitzgerald) were used for immunofluorescence; rabbit polyclonal C-115B (sc504; Santa Cruz Biotechnology, Inc.) was used for Western blotting. Antibodies to tyrosine-phosphorylated VEGFR-2 were rabbit polyclonal PY1214 and PY1054/59 (BioSource International) and rabbit polyclonal PY1175, which was provided by M. Shibuya (University of Tokyo, Tokyo, Japan). Antibodies to clathrin heavy chain were mouse monoclonal cloneX22 (Affinity BioReagents, Inc.) for immunofluorescence and mouse monoclonal clone 23 (R&D Systems) for Western blotting. Antibody to EEA-1 was goat polyclonal N-19 (Streptomyces filipinensis) for immunofluorescence and mouse monoclonal clone 23 (R&D Systems) for Western blotting. Antibody to SV783-PLCγ, total p42/44 MAPK, and phospho-p42/44 MAPK was rabbit polyclonal (Cell Signaling). Antibody to DEP-1/CD148/CD148 was goat polyclonal (R&D Systems), and antibody to PV-1 was rat monoclonal [provided by R. Sten, Dartmouth Medical School, Lebanon, NH].

Cell types and culture conditions

Endothelial cells with a homozygous null mutation of the VEC gene (VEC null) and the cell lines derived from them through retroviral gene transfer and expressing wild-type (VEC positive) or various VEC mutant constructs were generated and characterized as described previously in detail (Lampugnani et al., 2003). For all of the experiments, 50,000 cells/cm² were generated and characterized as described previously in detail (null) and the cell lines derived from them through retroviral gene transfer.

Cell types and culture conditions

VEGFR-2 gene (VEC

Cell types and culture conditions

Filipin and hypertonic treatments

Caveolae organization was altered by treatment with 1 μg/ml filipin (filipin III from Streptomyces filipinensis; Sigma-Aldrich) for 1 h (Schnitzer et al., 1994; Andriopoulou et al., 1999). Clathrin pit-mediated endocytosis was inhibited using hypertonic medium (0.45 M sucrose in MCDB 131 with 1% BSA) for 30 min to affect as described previously (Heuser and Anderson, 1989; Ehrlich et al., 2001). Cells were then stimulated and assayed as indicated in the specific sections.

RNA interference

Cells were seeded as described in Cell types and culture conditions. 20 h later, cells were washed once with OptiMEM (Life Technologies) and transfected with 40 nM of Stealth oligonucleotides (Invitrogen) using 2 μl/ml LipofectAMINE 2000 (Invitrogen) in OptiMEM according to the manufacturer’s instructions. After 5 h, the transfection medium was removed, and complete culture medium was added. Cells were cultured for a further 72 h before stimulation and processing for immunofluorescence and Western blotting.

Stealth oligonucleotides were used as follows: a, 5′-GCAUUGUUGUUCAUAACCUUUA-3′ (start nucleotide was 2,118 bases downstream of the start codon); b, 5′-GAAGAACCUCUUGCGCCGAUAUA-3′ (start nucleotide was 1,284 bases downstream of the start codon) to target mouse clathrin heavy chain; and c, 5′-UCGACCCGACAGCAUGUUGGAAA-3′. Start nucleotide was at 4,023 bases downstream of the start codon to target mouse DEP-1/CD148. As a control, a Stealth siRNA-negative control duplex oligonucleotide (Invitrogen) with a C/G content equivalent to the positive oligonucleotide was used.

Internalization assays

Microscopy

Cells were treated in vivo with anti-VEGFR-2 antibody and acid washed before fixation (Ehrlich et al., 2001; Dí Guglielmo et al., 2003) as follows. We used monoclonal antibodies to the extracellular domain of human and mouse VEGFR-2 (see Primary antibodies) as described by the manufacturers to be devoid of biological activity. As this aspect was crucial to the assay, we tested the effect of these antibodies on basal and VEGF-stimulated phosphorylation and internalization of VEGFR-2. We found that these antibodies do not stimulate the phosphorylation of VEGFR-2 in either condition. These results are reported in Fig. S5 (available at http://www.jcb.org/cgi/content/full/jcb.200602080/DC1). Anti-mouse VEGFR-2 was dialyzed for 3 h against PBS (with one change) to remove azide. Cells were precooled for 30 min on ice and treated with 10 μg/ml of antibody for 1 h on ice with gentle agitation. Before stimulation, cells were washed with ice-cold 1% BSA in MCDB 131 to remove unbound antibody, and fresh medium was added. Cells were stimulated with 80 ng/ml VEGF and transferred to 37°C. After the indicated time intervals, cells were placed on ice and acid washed (three washes with ice-cold 50 mM glycine in Ca²⁺/Mg²⁺ HBSS, pH 2.5, and two washes with Ca²⁺/Mg²⁺ HBSS, pH 7.5) to remove the antibody from the cell surface. Cells were then fixed as described in Immunofluorescence microscopy. To reveal the distribution of the primary antibody, Alexfluo488-conjugated donkey anti–rabbit (Invitrogen) was used for the rat anti-mouse VEGFR-2. For the recombobinant Etagged anti–human VEGFR-2, rabbit anti–Etag (Abcam) followed by Alexfluo488-conjugated donkey anti–rabbit (Invitrogen) were used.

Cell surface biotinylation and immunoprecipitation

Internalization, recycling, and degradation were measured as described previously by Fabбри et al. (1999) with the following modifications. Cells were put on ice and washed three times with ice-cold PBS containing Ca²⁺ and Mg²⁺. Ca²⁺/Mg²⁺ PBS. For surface biotinylation, cells in Ca²⁺/Mg²⁺ PBS were treated with 0.5 mg/ml of thiol-cleavable Sulfo-NHS-S-S-Biotin (Pierce Chemical Co.) for 1 h on ice. They were then washed on ice twice with Ca²⁺/Mg²⁺ HBSS, pH 7.4, and 2,5, and two washes with Ca²⁺/Mg²⁺ HBSS, pH 7.5) to remove the antibody from the cell surface. Cells were then fixed as described in Immunofluorescence microscopy. To reveal the distribution of the primary antibody, Alexfluo488-conjugated donkey anti–rabbit (Invitrogen) was used for the rat anti-mouse VEGFR-2. For the recombinant Etagged anti–human VEGFR-2, rabbit anti–Etag (Abcam) followed by Alexfluo488-conjugated donkey anti–rabbit (Invitrogen) were used.

Surface biotinylation and immunoprecipitation

Internalization, recycling, and degradation were measured as described previously by Fabбри et al. (1999) with the following modifications. Cells were put on ice and washed three times with ice-cold PBS containing Ca²⁺ and Mg²⁺. Ca²⁺/Mg²⁺ PBS. For surface biotinylation, cells in Ca²⁺/Mg²⁺ PBS were treated with 0.5 mg/ml of thiol-cleavable Sulfo-NHS-S-S-Biotin (Pierce Chemical Co.) for 1 h on ice. They were then washed on ice twice with Ca²⁺/Mg²⁺ PBS, once with MCDB 131, and once with 1% BSA MCDB 131. 80 ng/ml VEGF in fresh 1% BSA MCDB 131 was added, and cells were incubated at 37°C for the time indicated to allow internalization. The cultures were then put back on ice and washed three times with ice-cold Ca²⁺/Mg²⁺ PBS. Samples were incubated twice for 20 min with 45 μM of the membrane-permeable reducing agent GSH in 75 mM NaCl, with 75 mM NaOH and 1% BSA added just before use (stripping buffer). Cells were further washed twice on ice with Ca²⁺/Mg²⁺ PBS and incubated for 15 min with iodoacetamide [in Ca²⁺/Mg²⁺ PBS with 1% BSA, quenching buffer] to quench free sulfhydryl groups. To evaluate total labeling, a sample for each cell type was not reduced with GSH. To control background, a sample was labeled and reduced without incubation at 37°C. For immunoprecipitation, cells were washed with Ca²⁺/Mg²⁺ PBS and extracted on ice in 50 mM Tris-HCl, pH 7.6, 150 mM NaCl, 1% Triton X-100, 1% NP-40, and a cocktail of protease inhibitors (Set III; Calbiochem). Extracts were preclarified for 90 min with protein A–agarose beads and incubated overnight with 5 μg anti–VEGFR-2 rabbit sc504 and the immunocomplexes were collected on protein A–agarose beads for 90 min. After five washes in extraction buffer (the last one containing 0.1% Triton X-100), proteins were eluted by boiling for 10 min in nonreducing laemmli sample buffer. Samples were analyzed by SDS-PAGE followed by Western blotting on nitrocellulose membrane and revealed by ECL chemiluminescence. Band intensity was quantified by Imagej analysis (National Institutes of Health; freely available at http://rsb.info.nih.gov/ij/).
To quantify VEGFR-2 recycling and degradation, cells were labeled as described in the first paragraph of this section, and endocytosis was allowed for 10 min in the presence of 80 ng/ml VEGF (peak time for VEGF-induced VEGFR-2 internalization both inVEC-null and -positive cells as determined in internalization experiments). Samples were then reduced as described in the first paragraph of this section to remove the label from the residual cell surface receptor. The internalized fraction was chased by reincubation at 37°C with a Dounce homogenizer. Nuclei and residual intact cells were reduced to evaluate the amount of VEGFR-2 that recycled back to the plasma membrane, and the other sample was left unreduced to measure degradation. The samples were then processed as described in the first paragraph of this section. VEGFR-2 degradation was calculated by subtracting the value of residual biotinylated receptor after incubation at 37°C without proteolysis (i.e., internalized – recycled – degraded) from the total pool of internalized receptor. VEGFR-2 recycling was calculated by subtracting both the degradation value and the value of residual biotinylated receptor after incubation at 37°C and reduction (i.e., internalized – recycled – degraded) from the total pool of internalized receptor.

**Immunofluorescence microscopy**

Cells were cultured in 35-mm diameter petri dishes as described in Cell types and culture conditions. After the treatments indicated in the specific sections, culture medium was removed, and cells were fixed in 1% PFA in 2.5 mM triethanolamine, pH 7.5, containing 0.1% Triton X-100 and 0.1% NP-40 for 20 min at RT (Lallemand et al., 2003). Before staining, 0.5% Triton X-100 in PBS was added for 10 min at RT. In some experiments, immunofluorescence microscopy for VEGFR-2 was performed using the Alexa488- or Alexa647-labeled secondary antibodies produced in donkey had minimal cross-reactivity with markers of specific compartments such as EEA-1 and caveolin-1. A comparison of VEGFR-2 vesicular distribution after in vivo staining (with and without acid wash before fixation) is shown in Fig. S5.

In some experiments [in particular for clathrin detection], fixation was performed in 1% PFA, and permeabilization was performed with 0.02% saponin that was maintained for all of the staining procedure. Fluorophore-labeled secondary antibodies produced in donkey had minimal cross-reactivity to other species except for the targeted species (Invitrogen). Anti-VEGFR-2 was revealed with AlexaFluor488-conjugated secondary antibodies (anti-rat for anti-mouse VEGFR-2 and anti-rabbit for anti-human VEGFR-2). In double labeling experiments, AlexaFluor488- and -647 fluorochromes were used to stain each of the two antigens, respectively. Samples were observed under a confocal microscope (DMAR-Leica) using 63× and 100× lenses. Images were captured using a charge-coupled camera (model 3; Hamamatsu) before processing through Adobe Photoshop for Macintosh. Quantification of vesicular labeling was performed using the ImageJ program (version 10.2). For comparison purposes, different sample images of the same antigen were acquired under constant acquisition settings. The best-fit lower threshold to eliminate most of the signal background was determined using the threshold tool and confirmed by visual inspection and count of one-pixel dimension particles. In some cases, the same sample was analyzed at different lower thresholds to determine the best fit. Upper threshold was always set at 255. Particles with a minimum size of five pixels were counted. For colocalization analysis, images were acquired using a confocal microscope (TCS SP2 AOBS; Lyra) with a 63× objective and a 3× zoom. Colocalization was quantified using the colocalization plugin of ImageJ. The channel ratio was always set at 90%. For both channels, the best-fit lower threshold value to remove most background signal was determined using the threshold tool as described above.

**EM**

For immunogold labeling, 4% PFA/0.4% glutaraldehyde in PBS was added and processed for ultrathin cryosectioning as described previously (Conflonier et al., 2000). Double immunogold labeling was performed as described previously (Slot et al., 1991).

**Flasks**

As described in Cell types and culture conditions. Three flasks per gradient were used. After the indicated treatments, cultures were put on ice and washed twice with ice-cold PBS. Cells were scraped in 1.2 ml of ice-cold isotonic buffer/flask (20 mM Hepes-KOH, pH 7.5, 0.25 M sucrose, 90 mM KO-acetate, 2 mM Mg-acetate, 0.5 mM Na-vanadate, 1 mM NaF, 10 mM pyrophosphate, 3 mM Mg-cytophosphatase, 1 mM pefabloc, 40 U/ml aprotinin, 10 μg/ml leupeptin, and 10 μg/ml pepstatin) and homogenized with a Dounce homogenizer. Nuclei and residual intact cells were pelleted by centrifugation at 1,400 g for 5 min at 4°C. The supernatants were separated in three equal aliquots and mixed with iodoxalin (OptiPrep; Axis-Shield) and homogenization buffer to generate 30, 20, and 10% iodoxalin solutions. They were then loaded into 11.2-mL OptiSeal tubes (Beckman Coulter) and ultracentrifuged at 353,000 g for 3 h (a maximal 1 × 10^7 g/cm²). 600-μL fractions were collected from the top of the gradient, and protein concentration (bicinchoninic acid reagent; Pierce Chemical Co.) and density (OD at 244 nm as indicated by the OptiPrep manufacturer) were determined. The fractions were then boiled in the presence of reducing laemml sample buffer. Samples of each fraction containing the same amount of protein for the different cell types to be compared and representative of the total protein content of each fraction were analyzed by SDS-PAGE followed by Western blotting.

For total cell extracts, cells were washed twice in PBS, extracted in 2× boiling laemml sample buffer (200 μl for a 35-mm petri dish) containing 100 mM DTT, scraped, and boiled for a further 10 min. Parallel samples were extracted without DTT, and protein concentration was determined by bicinchoninic acid analysis. A total of 15 μg of protein was loaded in each lane and separated by SDS-PAGE, transferred onto nitrocellulose, and immunoblotted with the indicated antibodies.

For detection, HRP-conjugated horse anti-mouse, goat anti-rabbit (Cell Signaling), and rabbit anti-goat (DakoCytomation) secondary antibodies and ECL chemiluminescence reagent (GE Healthcare) were used. Films were scanned and bands were quantified using ImageJ set on the uncalibrated OD function. Adobe Photoshop 7.0, Excel X for Macintosh, and Adobe Illustrator 11 for the PC were used to produce the figures presented.

**Online supplemental material**

Fig. S1 shows that PV-1 colocalizes with caveolin in VEC-null and -positive cells. Fig. S2 shows that cell confluence modulates VEGF-induced PV-1/VEGFR-2–positive compartments in HUVECs. Fig. S3 shows that clathrin siRNA inhibits the formation of clathrin-positive vesicular compartments. Fig. S4 shows that the cytoplasmic domain of VEGFR-2 is required to modulate VEGFR-2 internalization from the plasma membrane. Fig. S5 shows that the antibody Avas 12.a 1 does not modify either the basal or VEGF-stimulated tyrosine phosphorylation of VEGFR-2 and does not induce VEGFR-2 internalization. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.200602080/DC1.

We are most grateful to Kendra Swirski for editing the manuscript. This work was supported by the Associazione Italiana per la Ricerca sul Cancro, the European Community (Integrated Project Contract LSHT-CCT2004-5035-7, NoE MAIN 502953, and NoE EVGN 503254), Italian Ministry of Health, Ministero dell’Università e della Ricerca/Fondo degli Investimenti della Ricerca di Base (grants RBNE01MVW_009 and RBNE01F1IT_007), and the Cariplo Foundation. C. Tacchetti received a grant from the Telethon Foundation (GTF03001).
