Stable Isotopes in Fish Eye Lenses as Potential Recorders of Trophic and Geographic History

Amy A. Wallace*, David J. Hollander, Ernst B. Peebles

Abstract

We evaluated eye lenses as potential recorders of stable isotope histories in fish because they consist of metabolically inert optical proteins that are deposited in successive, concentric circles (laminae) much like otolith circuli and tree rings. We conducted four different tests on lenses from red snapper, red grouper, gag, and white grunt. The first test was a low-resolution screening of multiple individuals (4–5 radial groups of laminae per lens, all species except white grunt). Along the radial axis, all individuals exhibited substantial isotopic variability. Red snapper individuals separated into two groups based on δ13C and δ15N, and gag separated into two groups based on δ13C. Two gag with the greatest variation were chosen for high-resolution temporal analysis using individual laminae from their second eye lenses. The first-order patterns from the high-resolution analysis generally mimicked patterns from the low-resolution screening of grouped laminae, yet the high-resolution plots revealed early-life details that were not apparent in the low-resolution screenings. For the third test, left- versus right-eye variation was compared using high-resolution methods. White grunt left- and right-eye radial isotopic patterns were almost identical for both δ13C and δ15N, suggesting the variations observed among individual fish were not artifacts. The final test evaluated intra-laminar variation; multiple samples were analyzed from different parts of the same lamina. Seven laminae from three individuals of two species were analyzed in this manner; variations among laminae were found to be much higher than variations within laminae. However, nominal intra-laminar variations were comparable to nominal differences between left and right lenses, suggesting intra-laminar variation established measurement precision. Eye lens isotopes appear to be useful for reconstructing the isotopic histories of individual fish; these histories can be compared with spatially-derived isoscapes to reconstruct individual histories for site fidelity, movement and trophic position.

Introduction

Internally recorded stable-isotope histories can be used to recreate lifelong trends in animal diets, trophic dependences, and movement within isotopically variable landscapes [1–5]. Such lifelong records are difficult to obtain because most tissues undergo metabolic turnover, and this turnover places limits on the retrospective time period that can be investigated [2,3,5,6,7].

Otoliths, fish scales, and vertebrate are tissues currently used to provide life-history records for fish. Otoliths are used to determine fish age and to reconstruct aquatic environments [9,9]. Otoliths grow during the entire life of the fish and consist of calcium carbonate deposited within a proteinaceous matrix. Otolith protein is generally not abundant enough (3–4% by weight) to allow retrospective δ15N comparisons [10]. Fish scales grow during most of the life of the fish and provide a nonlethal way to measure isotopic ratios. Fish scales overlap old organic material with new material during growth in a phenomenon called “overplating” [11,12,13]. Overplating affects isotopic ratios by combining isotopic values from new and old material; scales may not provide a true representation of isotopic information on a temporal scale [11]. Some researchers have explored the use of vertebral in sharks for stable-isotope analyses with encouraging results [14–16]. The collagen extracted from cartilaginous vertebrae is preserved because cartilage has low metabolic activity (little or no turnover) and it deposits in sequential layers [17]. However, this approach cannot be applied to the vertebrae of bony fishes because bone collagen is reworked over time [2,3]. Although this paper focuses on fish, it should be noted that there are a number of isotopic records for terrestrial animals as well. These include claws, hooves, hair, feathers, and teeth [18,19]. Although these tissues are isotopically conservative, the period of time represented by the record varies with tissue wear (e.g. claws, hooves) and replacement (e.g. feathers, hair) [18,19]. Some tissues can be sampled non-invasively on a regular basis to create a long-term isotopic record, but require recapitulation of the same animal on a regular basis [18,19].

In this paper, we evaluate fish eye lenses as potential recorders of the isotopic histories of individual fish; the eye lenses of squid (invertebrates) also appear to have this potential [20,21]. Vertebrate eye lenses are largely composed of different forms of a structural protein, crystallin, that develop in layers (laminae) at the outer lens as the animal grows [22,23]. During the mid-to-late gastrula stage, lens cells derive from surface ectoderm and
differentiate into two cell types, lens epithelial cells and fiber cells [24,25], although Bloemendal considered all lens cells to be epithelial [26]. At the surface of the lens, epithelial cells form a one-cell-thick outer layer (lens epithelium) adjacent to the fiber cells. Fiber cells remove their cytoplasmic organelles, including the cellular nucleus and its DNA, to establish and maintain optical transparency within the lens [22–25,27]. This process is a specialized form of apoptosis known as “attenuated” apoptosis, where the organelles are removed from the cell over a period of days, leaving behind the crystallin and other proteins [25,28]. Attenuated apoptosis is different from “classical” apoptosis in which everything, including the cell membrane, is degraded [25].

Fish eye lenses are spherical, and lens fiber cells are laid down in concentric layers much like the layers of an onion [22–24]. Fiber cells increase in length as the animal grows, but the increase in length is a step function of lens radius rather than a continuous increase, and this step function creates the physical discontinuities that are visible between adjacent laminae [22,27]. The oldest part of the lens is at the center (lens nucleus); the nuclear fiber cells are among the oldest cells in the body [25]. The outermost margin of the lens is the youngest material in the lens. De novo protein synthesis ceases following attenuated apoptosis [22]. Crystallins and other lens proteins are rich in both carbon and nitrogen, and thus are suitable for δ¹³C and δ¹⁵N analysis; this contrasts with otoliths, which are nitrogen-poor. Eye lenses thus have the potential to allow reconstruction of lifetime δ¹³C and δ¹⁵N histories and their associated ecological interpretations.

To investigate variation in fish eye-lens stable isotopes, we selected fish species that occur in geographic locations that had already been the subject of isotopic mapping (isotope maps are known as “isoscapes”). This allowed comparison of any observed isotopic trends within the fish eye lenses with a known range and pattern of isotopic variation documented by Radabaugh et al. [29]. Four species (red snapper, red grouper, gag, white grunt) were selected that have life histories and their associated ecological interpretations.

Four types of isotopic variation were plotted: 1) low-resolution screening plots, 2) high-resolution plots for selected, screened individuals, 3) plots of left vs. right eyes, and 4) plots of variation within individual laminae (intra-laminar variation). For low-resolution screening, eye lenses were separated into 4–5 sections using fine-tip forceps, with multiple laminae intentionally included within each section; the number of true laminae constituting each
Figure 1. Low-resolution screening. Rapid screening of specimens to detect large-scale differences in isotopic history. Each plotted line is a different specimen; lines are labeled with specimen numbers. doi:10.1371/journal.pone.0108935.g001
section was not known. For all other tests, an effort was made to subdivide the lenses into the smallest thicknesses that were manually practical (“laminae”). Individual sections and laminae were stored separately in 1-dram glass vials. Laminae became desiccated in 1 h at 25°C, after which most samples were homogenized using a mortar and pestle; exceptions were laminae that were haphazardly selected for intra-laminar variation analysis, which were subdivided first and then homogenized.

Dried laminae were weighed to the nearest mg on an analytical balance. A dry weight of 300–600 mg of material was placed in tin capsules for combustion and isotopic analysis. 13C/12C and 15N/14N and C:N were measured in replicate using a Carlo-Ebra NA2500 Series II elemental analyzer coupled to a continuous-flow ThermoFinnigan Delta+XL isotope ratio mass spectrometer at the University of South Florida College of Marine Science in St. Petersburg, Florida. The lower limit of quantification was 12 mgC or N. Calibration standards were NIST 8573 and NIST 8574 L-glutamic acid standard reference materials. Analytical precision, obtained by replicate measurements of NIST 1377b bovine liver, was ±0.11 % for δ13C and ±0.19 % for δ15N (average standard deviations of n = 30 replicates). Results are presented in standard notation (δ, in %) relative to international standards Pee Dee Belemnite (PDB) and air:

\[
\delta^{\text{i}}X = \frac{\langle X \rangle_{\text{sample}}}{\langle X \rangle_{\text{standard}}} - 1 \]

where \(X\) is the element and \(i\) and \(j\) are each an isotope of \(X\).

Data Location and Analysis

All data are published at the Gulf of Mexico Research Initiative Information and Data Cooperative (https://data.gulfresearchinitiative.org/data/R1.x135.120:0006). In all comparisons except for the intra-laminar comparison, replicate isotope measurements were averaged and plotted for descriptive purposes. In the intra-laminar comparison, the objective was to determine if inter-laminar variation was greater than intra-laminar variation; individual replicate isotope measurements were compared among laminae using one-way ANOVA. Individual laminae were compared using 95% Tukey HSD intervals as a multiple range

Figure 2. Low- and high-resolution comparison. The low-resolution screening method (analysis of coarse lens layers) is compared with the high-resolution method (analysis of individual laminae) for gag 2 (upper panels) and gag 38 (lower panels). The leftmost observation in the high-resolution method is for the lens nucleus; the remaining observations are for individual laminae. Gag 2 was 704 mm total length (TL); gag 38 was 832 mm TL. Both were female.

doi:10.1371/journal.pone.0108935.g002
test (Statgraphic Centurion, v. 16.2.04). In all comparisons, means and replicates were plotted without any exclusion.

**Results**

Low-resolution screening analyses were conducted for eight red snapper, four red grouper, and three gag. All individuals had variable isotopic values among lens layers (Figure 1). The majority of values were centered within ranges reported by Radabaugh et al. [29] for trawl-caught demersal fishes on the West Florida Shelf (−19−−14 % δ¹³C; 7–13.5% δ¹⁵N). Red snapper appeared to form two groups based on their δ¹⁵N values; fish 45 and 47 (Figure 1) had consistently high δ¹⁵N values. There were no clear groupings in red grouper. Gag 2 had higher δ¹³C values for its innermost layer than the other two gag, and all three gag had isotopic values that converged in the outermost layers.

Gag 2 and 38 were analyzed using high-resolution analysis to further evaluate the difference recorded in the innermost layers. The second lens from gag 2 (3.1 mm radius) was dissected into 14 laminae plus a lens nucleus of 0.65 mm radius, indicating an average laminar thickness of 175 μm. The second lens from gag 38 (3.2 mm radius) was dissected into 16 laminae plus a lens nucleus of 0.60 mm radius, indicating an average laminar thickness of 163 μm. When data from the two lenses were combined, dry weight (DW, in mg) increased as $DW = 3.24r^3$ ($n = 32$, $R^2 = 0.99$, $p < 0.0001$), where $r$ is lens radius in mm. The mean dry density of these two gag lenses was 0.89 mg mm$^{-3}$. Laminar thickness varied at a sub-annual scale in these two specimens, but did not have a strong positive or negative overall relationship with lens radius (slope $p > 0.05$).

The exponential (cubic) increase in average laminar weight that accompanies increasing lens size translates into a mass-balanced bias toward outer laminae when groups of laminae are processed together as a collective layer (e.g., during low-resolution screening analysis). The innermost layer from the screening analysis was most likely to be misrepresentative of patterns observed in the high-resolution analysis (Figure 2). Nevertheless, the screening method indicated different incipient δ¹⁵N values for gag 2 and 38, and this difference was borne out by the high-resolution analysis, albeit at a nominally lower difference (2.5 vs. 3.0 %).

The left lens of white grunt 2 was dissected into 12 laminae plus the lens nucleus. The radius of the left lens nucleus was 0.50 mm and the radius of the whole left lens was 2.85 mm, indicating a mean laminar thickness of 196 μm. The right lens was dissected into 13 laminae plus the lens nucleus. The radius of the right lens nucleus was 0.60 mm and the radius of the whole right lens was 2.88 mm, indicating a mean laminar thickness of 175 μm. Isotopes in both eyes were centered within ranges reported by Radabaugh et al. [29], and δ¹⁵N increased during life; this latter trend was observed in 15 of the 16 fish examined (94%, with red snapper 45 being the sole exception). Isotopic patterns were very similar between left and right eyes (Figure 3), yet plotted pairings of radial midpoints in Figure 3, average laminar thicknesses (196 vs. 175 μm), and the difference in total lamina count (12 vs. 13) were not in perfect agreement. One-way ANOVA indicated inter-laminar variation (Figure 4) was much larger than intra-laminar variation.
variation for both $\delta^{13}C$ \( F(6,16) = 40.6, p<0.0001 \) and $\delta^{15}N$ \( F(6,16) = 232.4, p<0.0001 \).

A total of 197 samples were analyzed (72 sections, 125 laminae). The range of mass C:N was 2.72–3.37. The mass C:N mean value was $2.97 \pm 0.12$ (molar C:N range = 3.17–3.39; mean = $3.46 \pm 0.14$). The C:N ratio was consistently $<3.5$; therefore, no lipid correction or normalization was needed because the lipid concentrations were uniformly low [33].

**Discussion**

The results indicate low-resolution isotopic screening has strong potential as an index of broad-scale changes in the isotopic history of individual fish. Broad-scale changes were evident in all species, yet red snapper and gag appeared to originate from distinct groups that converged later in life (all fish were collected from the same geographic region). The magnitude of isotopic variation observed in both the low- and high-resolution tests (Figures 1–3) matches the scale of variation in isoscapes produced by Radabaugh et al. [29] for the West Florida Shelf, the region from which the fish in our tests were collected. The low-resolution screening tests were rapid and cost-effective, but sometimes missed important life events. In the case of the gag (Figure 2), the missed detail involved early life history; for gag 2, the low-resolution analysis had a starting value of $-13.8 \%$ for $\delta^{13}C$ while the high-resolution analysis was variable, starting at $-16.4$ and increasing to $-12.9 \%$. The high-resolution approach contains the most information that can be obtained practically using the manual delamination method.

The white grunt’s left and right eyes identified very similar lifelong trends (Figure 3), suggesting the temporal trends observed in the other comparisons (e.g., Figure 1) were repeatable and were not artifacts. The scale of variability between left and right eyes was similar to that of intra-laminar variation. Most intra-laminar variation was less than the instrument error calculated using bovine liver ($\pm 0.11 \%$ for $\delta^{13}C$; $\pm 0.19 \%$ for $\delta^{15}N$). Small, intra-laminar variation likely impacts a limit to the precision of the overall method.

All of the values and trends in the eye-lens isotopes are consistent with expected life-history patterns and trophic positions, as interpreted using published $\delta^{13}C$ and $\delta^{15}N$ isoscapes for demersal fish muscle [29]. Isoscapes visually portray spatial isotopic variation within natural systems [34]. While many terrestrial isoscapes exist, a need exists for developing more marine isoscapes [35]. When eye-lens isotopes are compared to observed and modeled isoscapes for demersal fish muscle on the West Florida Shelf [29,36], it appears that the two red snapper with higher $\delta^{15}N$ (Figure 1) traveled from the northern end of a $\delta^{15}N$ latitudinal gradient, and those with lower $\delta^{15}N$ traveled from or remained within more southerly waters. Isoscape trends in $\delta^{13}C$ of demersal fishes are more depth-related (higher values in shallow water) than latitude-related [29]. Red snapper eye-lens $\delta^{13}C$ remained below $-15.5 \%$ throughout life, which is consistent with the red snapper’s known preference for deeper water on the middle and outer portions of West Florida Shelf. The three gag may have started life at different locations, but spent a lengthy period of time together before collection. Unlike the red snapper, the gag uses shallow inshore waters as nursery habitat [37].
validating diet relationships with eye-lens isotopes. However, the fish may be particularly definitive both for aging eye lenses and for eye lenses for accuracy because spatial stationarity cannot be term geographic histories for individual fish by combining isotope stable isotope analysis of the both the trophic and source amino acids within different laminae [42–44]. 5) determination of long-term geographic histories for individual fish by combining isotope histories, knowledge of how trophic level changes with age ( trophic growth rate), and output from isotope models [36]; modeled isotope outputs must be synchronized with time periods within eye lenses for accuracy because spatial stationarity cannot be assumed [36,45]. 4) comparing isotopic fractionation of eye lens tissues with fractionation of other tissues [46,47]. Studying captive fish may be particularly definitive both for aging eye lenses and for validating diet relationships with eye-lens isotopes. However, the production and accurate interpretation of long-term geographic histories for individual fish require that eye-lens aging and trophic growth rate studies be completed first.

While our ability to rigorously interpret geographic histories from the eye-lens isotope data is limited by the present lack of the aforementioned studies, the patterns of variation within the eye lenses (Figs. 1–4) indicate that the overall approach is promising. There is no other known source of simultaneous $^{13}$C and $^{15}$N temporal records within bony fish. The approach presented here is not necessarily limited to bony fish, and may also be applied to other vertebrates as long as the spatiotemporal distribution of apoptosis within the lens is taken into consideration. In fish, TUNEL assays (terminal deoxynucleotidyl transferase dUTP nick-end labeling) indicate that even recently formed laminae can be apoptotic and therefore isotopically conservative [24], whereas humans and other higher vertebrates may contain large proportions of pre-apoptotic (potentially non-conservative) cells in the outer cortical region of the lens.
