Abstract

We address the problem of unpaired geometric image-to-image translation. Rather than transferring the style of an image as a whole, our goal is to translate the geometry of an object as depicted in different domains while preserving its appearance characteristics. Our model is trained in an unpaired fashion, i.e. without the need of paired images during training. It performs all steps of the shape transfer within a single model and without additional post-processing stages. Extensive experiments on the VITON, CMU-Multi-PIE and our own FashionStyle datasets show the effectiveness of the method. In addition, we show that despite their low-dimensionality, the features learned by our model are useful to the item retrieval task.

*This manuscript is a pre-print currently under review at the Elsevier Journal Computer Vision and Image Understanding.

1. Introduction

1 Image-to-image translation (I2I) refers to the process of generating a novel image, which is similar to the original input image yet different in some aspects. Typically, the input and output images belong to different domains, with images in the same domain sharing a common characteristic, e.g. going from photographs to paintings ([20]), from greyscale to color images ([5]), or from virtual (synthetic) to real images ([45]). Apart from direct applications ([23]), I2I has proven valuable as a tool for data augmentation ([7]) or to learn a representation for cross-domain image retrieval ([11]).

Traditionally, each image domain is characterized by a different appearance or style, and I2I is therefore sometimes referred to as style transfer ([20]). While the translation process may drastically change the appearance or style of the input image, the image semantics are to be preserved, i.e.

![Figure 1. Translating a clothing item from a "catalog" image domain to a domain of individuals wearing the indicated item (try-on task, top), and vice versa (take-off task, bottom). Notice how for both tasks the appearance details of the clothing items are preserved while their shape is effectively translated.](image.png)
to domains that share the same geometrical information. Instead, we work with one object-centric domain with standard shape and one that is more contextualized with large shape variation (using a reference image to provide the right context). For instance, we go from a single piece of clothing to a person wearing that same item; or from a frontal face crop to a wider shot with arbitrary viewpoint of that same person (see Fig. 1 & 11). This setting is significantly more challenging, as the image geometry changes. At the same time, the image semantics (e.g. the clothing pattern or face identity) should be preserved. Analogous to the term style transfer, we refer to this as shape transfer. While a couple of recent works have looked into this setting ([33, 42, 44]), to the best of our knowledge we are the first to propose a solution that does not require paired data, across different domains, for model training. This is important, as collecting paired data is cumbersome or even impossible. Either way, it limits the amount of data that can be used for training, while access to large amounts of data is crucial for the quality of the results. Methods working with unpaired training data have been proposed for style transfer ([16, 46]), relying on low-level local transformations. However, these are not suited for the more challenging shape transfer setting, as clearly illustrated in Fig. 2.

Translating shapes in a unpaired way is an unsolved task that is of interest for several reasons. First, it can be considered an alternative formulation of the novel-view synthesis problem, in the 2D image space, using only a single image as input. Second, shape translation can recover missing/occluded characteristics of an object instance which can help other tasks, such as recognition or tracking.

Beyond providing a wider comparison w.r.t. existing work, finer level of detail in the presentation, extended experiments and deeper discussions, here we extend our recent work ([39]) along four directions. First, we conduct an ablation study highlighting the importance of the different components of the proposed method (Sec. 4.1). Second, we perform an additional ablation study bridging the performance of our method w.r.t. similar methods from the literature, namely MUNIT ([16]) (Sec. 4.4). Third, we assess the capability of the proposed method at translating shapes across images of faces (Sec. 4.6). Finally, we conduct a deep evaluation to assess the performance of the representations learned by the proposed method for the task of content-based image retrieval (Sec. 4.5).

The main contributions of this paper are four-fold: i) We analyze the task of unpaired shape translation. To the best of our knowledge, we are the first doing this from an unpaired perspective. ii) We propose an unpaired shape transforming (UST) method, which does not need any paired data or refinement post-processing. In one stream, an object with standard shape is transformed to a contextualized domain with arbitrary shape, and vice versa in the other stream. iii) We achieve a one-to-many mapping by utilizing context and structure information guidance. iv) We show the potential of the features learned by our model on the cross-domain item retrieval task.

This paper is organized as follows: Sec. 2 positions our work in the literature. In Sec. 3 we present the details of the proposed method. This is followed by an extensive evaluation in Sec. 4. Finally, we draw conclusions in Sec. 5.

2. Related Work

[17] first formulate the image-to-image translation problem with a conditional GAN model which learns a mapping from the source image distribution to the output image distribution using a U-Net neural network in an adversarial way. [46] propose cycle-consistency to solve the I2I problem with unpaired data. This enables a lot of applications since it is usually expensive or even impossible to collect paired data for many tasks. [29] assume that there exists a shared latent space for the two related domains and propose a weights-sharing based framework to enforce this constraint. These methods learn a one-to-one mapping function, i.e. the input image is mapped to a deterministic output image. [16, 1, 31, 25] propose unpaired multimodal methods which either sample multiple styles from a Gaussian space or capture the styles from exemplar images to generate diverse outputs.

All the above methods focus on appearance transfer where the content depicted in the input and output images has an aligned geometric structure. [44, 14, 32, 33, 4, 36] aim at the case when the geometry itself is to be transferred. However, these methods focus on within-domain tasks (e.g. person-to-person and face-to-face), which depicts reduced variability when compared to its cross-domain counterpart (e.g. person-to-clothing). Focused on images of clothing items, [42] propose one of the first methods addressing cross-domain pixel-level translation. Their method semantically transfers a natural image depicting a person (source domain) to a clothing-item image corresponding to the clothing worn by that person on the upper body (target domain), and vice versa. Recently, [12, 38] propose two-stage warping-based methods aimed at virtual try-on of clothing items. These methods focus on learning a thin-plate spline (TPS) operation to transfer the pixel information directly. They rely on paired data to learn to transfer the shape in a first stage and then refine it in a second stage. In contrast, we propose a more general method that utilizes the context and shape guidance to perform translation across different domains without any paired data. In addition, different from previous works which divide the translation process into multiple stages, our method is able to handle the full appearance-preserving translation, in both directions, within a single model.

Outside of the I2I literature, [18] proposes a spatial trans-
former network (STN) which also aims at object-level transformations. Different from our method, which learns the plausible transformations from data and allows for user-suggested transformations through the use of “desired” target images, STNs start from a predefined set of possible transformations. In addition, STNs apply the same transformation to every pixel. Differently, our method implicitly allows deformable objects since different pixel-level transformations are possible as depicted in the training data. Finally, STNs makes no distinction between content and style information. Along the same line, recently [27] and [24] proposed methods focused on the image composition task. [27] learns how to add object segments with the correct shape in the semantic space. This is more constrained than our instance-level transfer in the RGB space. Moreover, it requires expensive supervision in the form of pixel-wise labels and instance-level contours. [24] operates in the RGB space. However, it can only handle homography transformations (in rigid objects) related to changes in viewpoint and scale. This is un-applicable on articulated/deformable objects and unsuitable to handle self-occlusions.

3. Methodology

In this section, we describe our model using the clothing try-on / take-off as an example. It should be noted though that our method can also be applied to other types of data, such as the face try-on / take-off illustrated in Sec. 4. Our goal is to transfer the shape information while keeping the appearance information, all trained without access to paired data. For this, we propose the asymmetric two-stream model shown in Fig. 3. The asymmetry reflects the fact that one of the two domains (domain B) is object-focused (e.g. catalog images of clothing items) while the other one (domain A) shows the objects in context (e.g. pictures of clothed persons). In the one-to-many try-on stream (blue arrows), we transfer from the object-focused to the contextualized setting. This requires synthesizing a new image, where the shape of the object is first altered after which it is merged seamlessly with the provided context (in our setting, a segmented image of a person wearing a different piece of clothing). During this process, the color, texture and anything else specific to the object instance is to be preserved. In the many-to-one take-off stream (red arrows), our goal is to synthesize the clothing catalog image in a standard frontal view starting from a natural person image with varying pose.

Here, we use \( x_A \) and \( x_B \) to refer to images from domain A and domain B respectively. \( x_{AB} \) refers to images transferred from domain A to domain B, and vice versa for \( x_{BA} \).

3.1. Assumptions

In previous works ([42, 12]), the try-on and take-off tasks are solved in a supervised way, respectively. Here, we solve both tasks in one model using unpaired data based on shared-latent space and context-structure constraints. **Shared-latent space constraint.** Similar to [16, 31, 25], we decompose the latent space into a content space and a style space. Different from previous works, we have two assumptions: 1) content space constraint, i.e. the content space \( \text{can be shared} \) by the two domains; 2) style space constraint, i.e. images from the two domains \( \text{do share} \) the same style space. We use \( Z_A^C \) and \( Z_B^C \) to denote the content space of domains A and B, respectively. We assume \( Z_A^C \) and \( Z_B^C \) are both embedded in a larger latent space \( Z_{\text{shared}}^C \). Symbols \( Z_A^S \) and \( Z_B^S \) denote the style space of domain A and B, respectively. Note that we assume \( Z_A^S \) and \( Z_B^S \) are the same space, which is a stronger constraint.

To achieve the content space constraint, we use two encoders \( E_A^C \) and \( E_B^C \) to encode images from domain A and B, respectively. Then, we use a latent content code reconstruction loss to enforce the latent content reconstruction, similar to [16, 25]. To achieve the style space constraint, we utilize both the weight-sharing technique ([29]) and the latent style code reconstruction loss (see Fig. 3). **Context constraint.** Although the above shared-latent space
constraints enable the unpaired I2I and work well for style transfer tasks ([29, 31, 25]), it is not enough for geometry transfer when the output is multi-modal (i.e. multiple possible outputs). To address this, [42] proposed triplet adversarial learning with paired data. However, for the unpaired setting, the adversarial learning on its own is too weak (see Fig. 2). Here, we propose to use context information guidance to constrain the output to be deterministic, i.e. decompose the one-to-many mapping into one-to-one mappings. In particular, for the try-on stream, we propose a Fit-in module which combines the feature maps with the context information. As to the take-off stream, we assume the output is deterministic (i.e. a one-to-many mapping). Decomposing the shape mask \( m_A \) with the inputs before \( G_A \) and the discriminator \( D_A \) (see Fig. 3).

3.2. Network architecture

The model can be divided into several sub-networks. For the content encoder \( E^C_A \) and \( E^C_B \), we use a convolution block and several down-sampling layers followed by several residual blocks. The decoders \( G_A \) and \( G_B \) are symmetric with the encoding part except for the Fit-in module which is key to learn the one-to-many mapping and the shape mask attention that helps preserving the appearance. The Fit-in module is a simple convolution block which receives the generated feature map and the context information of the desired target shape. The shared style encoding module contains a style encoder \( E^S_{shared} \) and a multilayer perceptron (MLP). It encodes the style information of both domains. For the try-on stream (MLP). It encodes the style information of both domains. For the try-on stream, the产生的特征图和上下文信息融合模块。在 parallel, for the take-off stream, we propose a Fit-in module which combines the feature maps with the context information. As to the take-off stream, we assume the output is unimodal and directly use the adversarial learning to learn the deterministic many-to-one mapping.

Attention. Since domain A is contextualized, we need to constrain the network to focus on the object instead of the background. Therefore, we introduce the attention mechanism in both generator and discriminator, i.e. concatenating the shape mask \( m_A \) with the inputs before \( G_A \) and the discriminator \( D_A \) (see Fig. 3).

\begin{equation}
\text{AdaIN}(z, \gamma, \beta) = \gamma \frac{(z - \mu(z))}{\delta(z)} + \beta,
\end{equation}

where \( z \) is the activation of the previous convolution layer. \( \mu \) and \( \delta \) are the mean and standard deviation computed per channel. Parameters \( \gamma \) and \( \beta \) are the output of the MLP of the shared style encoding module.

During decoding, the content code \( z^B_B \) concatenated with the shape mask \( m_A \) are fed to the decoder \( G_A \). There the
content and style are fused by AdaIN and then fed to the Fit-in module. We apply AdaIN in both the residual blocks and up-sampling layers. This helps stabilize and speed up the convergence during training, and also helps preserve appearance better. This is due to the fact that AdaIN can be treated as a skip-connection between the encoder and decoder to alleviate the exploding and diminishing gradient problems. The Fit-in module is designed to enforce the context information constraint. We first obtain the bounding box of the mask from the context image. Then, we resize and align the up-sampled feature maps to this bounding box. Finally, this output is concatenated with the context image. The main goal of this design is to integrate the context information which helps the deterministic shape transform. The final try-on image \( x_{BA} \) is generated after the last convolution block.

In addition, inspired by [17], we introduce an attention mechanism to both generator and discriminator. We concatenate the mask \( m_A \) with the content code \( z^c_A \) before the generator \( G_A \) and concatenate the mask \( m_A \) with the generated image \( x_{BA} \) before the discriminator \( D_A \), respectively. This simple but effective attention operation encourages the network to focus on the generated clothing instead of the context part. This improves the results, especially when the objects to be translated have a highly variable scale/location within the images.

**Take-off stream** For the take-off stream, the clothed person image \( x_A \) first passes through a convolution block and then gets multiplied with the clothing mask \( m_A \) in order to exclude the background and skin information. Similar to the try-on stream, the masked feature maps are then encoded into a content code \( z^c_A \) in the shared content space \( Z^c_{shared} \).

For the decoding part, the only difference with the try-on stream is that there is no "Fit-in" module or mask attention. The final take-off catalog image \( x_{AB} \) is generated by decoding \( z^c_A \), through the decoder \( G_B \) with AdaIN residual blocks, up-sampling blocks and convolution blocks.

### 3.3. Learning

In this section, we only describe A→B translation for simplicity and clarity. The B→A is learned in a similar fashion. We denote the content latent code as \( z^c_A = E^c_A(x_A) \), style latent code as \( z^s_A = E^s_{shared}(x_A) \), within domain reconstruction output as \( x_{AA} = G_A(z^c_A, z^s_A) \), cross domain translation output as \( x_{AB} = G_B(z^c_A, z^s_A) \). Our loss function contains terms for the bidirectional reconstruction loss, cycle-consistency loss and adversarial loss [16, 25]. Besides, we also use a composed perceptual loss to preserve the appearance information across domains, and a symmetry loss capturing some extra domain knowledge ([14, 44]).

**Bidirectional reconstruction loss** \( L_{LR}^x, L_{SR}^x \). This loss consists of the feature level latent reconstruction loss \( L_{LR} \) and the pixel level image self-reconstruction loss \( L_{SR} \). The former contains both content and style code reconstructions. The whole bidirectional reconstruction loss encourages the network to learn encoder - decoder pairs that are inverses of one another and also stabilizes the training.

\[
L_{LR}^x = E_{x_{AB}} z^c_A \left[ \| E^c_B(x_{AB}) - z^c_A \|_1 \right] + E_{x_{AB}} z^s_A \left[ \| E^s_{shared}(x_{AB}) - z^s_A \|_1 \right] \tag{2}
\]

\[
L_{SR}^x = E_{x_{BA}} \left[ \| x_{AA} - x_A \|_1 \right] \tag{3}
\]

**Adversarial loss** \( L_{GAN}^x \). To make fake images look domain realistic, we use an adversarial loss to match the domain distribution. For the A→B translation, the domain B discriminator \( D_B \) tries to distinguish the generated fake images with the real domain B images, while the generator \( G_B \) will try to generate domain B realistic images.

\[
L_{GAN}^x = E_{x_B} \left[ \log D_B(x_B) \right] + E_{x_B} \left[ \log (1 - D_B(x_B)) \right] \tag{4}
\]

**Cycle-consistency loss** \( L_{CC}^x \). To enable unpaired translation, the cycle-consistency loss [46] is applied to stabilize the adversarial training.

\[
L_{CC}^x = E_{x_{AB}} \left[ \| G_A(E^c_B(x_{AB}), E^s_{shared}(x_{AB})) - x_A \|_1 \right] \tag{5}
\]

**Perceptual loss** \( L_{P}^x \). To preserve the appearance information, we apply a composed perceptual loss.

\[
L_{P}^x = \left( E_{x_{AA}, x_A} \left[ \| \Phi(x_{AA}) - \Phi(x_A) \|_2^2 \right] \right) + \left( E_{x_{AB}, x_B} \left[ \| \Phi(x_{AB}) - \Phi(x_A) \|_2^2 \right] \right) + \lambda E_{x_{AB}, x_B} \left[ \| Gram(x_{AB}) - Gram(x_A) \|_1 \right], \tag{6}
\]

where \( x_A \) is the Region of Interest (RoI) of \( x_A \). For clothing items, it is the segmented clothing region. For the face experiments, it is the facial region (without context information). \( \Phi \) is a network trained on external data, whose representation can capture image similarity. Similar to [8] and [21], we use the first convolution layer of all five blocks in VGG16 [37] to extract the feature maps to calculate the Gram matrix which contains non-localized style information. \( \lambda \) is the corresponding loss weight.

**Symmetry loss** \( L_{Sym}^x \). To utilize the inherent prior knowledge of clothing and human faces, we apply a symmetry loss ([14, 44]) to the take-off stream.

\[
L_{Sym}^x = E_{x_{AB}} \left[ \frac{1}{W \times H} \sum_{w=1}^{W-1} \sum_{h=1}^{H-1} \| x_{AB}^{w,h} - x_{AB}^{W-(w-1),H-(h-1)} \|_1 \right], \tag{7}
\]

where \( H \) and \( W \) denote the height and width of the image, \( (w, h) \) are the coordinates of each pixel, and \( x_{AB}^{w,h} \) refers to a pixel in the transferred image \( x_{AB} \).

**Total loss.** Our model, including encoders, decoders and discriminators, is optimized jointly. The full objective is as follows,

\[
\min_{E^c_A, E^c_B, E^s_{shared}, G_A, G_B, D_A, D_B} \max_{D_A, D_B} \mathcal{L}(E^c_A, E^c_B, E^s_{shared}, G_A, G_B, D_A, D_B) = L_{GAN}^x + L_{SR}^x + \lambda_{CC}(L_{CC}^x + L_{X_{LR}}^x) + \lambda_{SR}(L_{SR}^x + L_{X_{SR}}^x) + \lambda_{LR}(L_{LR}^x + L_{X_{LR}}^x) + \lambda_{P}(L_{P}^x + L_{P}^y) + \lambda_{Sym}L_{Sym}^x \tag{8}
\]
where $\lambda_{CC}$, $\lambda_{SR}$, $\lambda_{LR}$, $\lambda_P$ and $\lambda_{Sym}$ are loss weights for different loss terms.

4. Evaluation

We evaluate our method on both clothing try-on / take-off and face try-on / take-off tasks. We perform an ablation study on our own FashionStyle dataset. Then, the full model results on VITON and MultiPIE datasets are reported. Finally, we assess the potential of the learned style/appearance representation for clothing item retrieval across domains. 

Datasets We use three datasets: VITON ([12]), FashionStyle and CMU MultiPIE ([10]). VITON and FashionStyle are fashion related datasets, see Figs. 1, 6, 7 for some example images. VITON has around 16,000 images for each domain. However, we find that there are plenty of image duplicates with different file names. After cleaning the dataset, there are 7,240 images in each domain left. The FashionStyle dataset, provided by an industrial partner, has 5,230 training images and 1,320 testing images of clothing catalog items (domain B). For domain A, FashionStyle has multiple views of the same person wearing the same clothing item. We present results on this dataset for one category, namely pullover/sweater. CMU MultiPIE is a face dataset under pose, illumination and expression changes. Here we focus on a subset of images with neutral illumination and expression, and divide the subset in two domains: 7,254 profile images (domain A) and 920 frontal views (domain B).

Metrics We use paired images from different domains depicting the same clothing item to quantitatively evaluate the performance our method. For the case of the try-on task we measure the similarity between the ROI of original image (from domain A) and the ROI of a generated version (where its corresponding clothing item has been translated to fit in a masked out version of the image). Thus, we call it Try-on ROI. To create this masked image we first run a clothing-item segmentation algorithm ([26]) that we use to remove the clothing-item originally worn by the person. For the case of the take-off task, given an image from domain A, we measure the similarity of its corresponding clothing item (from domain B) with the generated item. On both cases similarity between images is computed using the SSIM ([40]) and LPIPS ([43]) metrics. We report the mean similarity across the whole testing set.

For the retrieval task performance is reported in terms of Recall rate given that in our dataset every query image has only one corresponding image in the database.

Implementation details The perceptual feature extractors $\Phi$ in Eq. 6 are LPIPS ([43]) and Light-CNN ([41]) networks for clothing translation and face translation, respectively. In all our experiments, we use the Adam [22] optimizer with $\beta_1=0.5$ and $\beta_2=0.999$. The initial learning rate is set to $2\times10^{-6}$. Models are trained with a minibatch of size 1 for FashionStyle and VITON, and 2 for the face experiment. We use the segmentation method [26] to get the clothing mask and its bounding box. For faces, we detect the face landmarks using the detector proposed by [6] and then connect each point to get the face mask. The shared content code is a tensor whose dimension is determined by the data. The shared style code is a vector, we use $8/32/128$ dimensions in our experiments.

Table 1 summarizes the details of network architecture presented in Fig. 3 of the submitted manuscript. Furthermore, we specify the training parameters used for the tasks analyzed in our experiments. The number of input/output convolution blocks is set to $n_1 = 1$. The number of down-sampling and up-sampling convolution blocks is set to $n_2 = 3$ and $n_2 = 2$ for clothing and face translation, respectively. We need a different value here, since the images from the two datasets have different resolutions. The number of residual blocks is set to $n_3 = 4$ for both clothing and face translation experiments. As for our Fit-in module, it consists of one residual block to merge the features with the context information.

| Parameter | Clothing try-on | Clothing take-off | Face try-on | Face take-off |
|-----------|----------------|------------------|-------------|--------------|
| $n_1$     | 1              | 1                | 1           | 1            |
| $n_2$     | 3              | 3                | 2           | 2            |
| Minibatch | 4              | 4                | 4           | 4            |
| Learning rate | 4e-5          | 4e-5             | 4e-5        | 4e-5         |
| $\lambda_{CC}$ | 5             | 5                | 5           | 5            |
| $\lambda_{SR}$  | 10             | 10               | 10          | 10           |
| $\lambda_{LR}$  | 10             | 10               | 10          | 10           |
| $\lambda_{Sym}$ | 2.5            | 0.075            | 0.025       |
| $\lambda_P$    | 2e-4           | 2e-4             | 6e-5        | 2e-6         |
| Iteration    | ~60k           | ~60k             | ~60k        | ~60k         |

4.1. Ablation Study: Clothing try-on / take-off

We conduct a study in order to analyze the importance of four main components of our model. More precisely, the perceptual loss, shared style encoder (Shared S. E.), mask attention and Fit-in module, on the FashionStyle dataset. Note that mask attention is applied to generator $G_A$ and discriminator $D_A$. Towards this goal we test different variants of our architecture (Sec. 3) where one of these four components has been removed. In addition, we run an experiment using a supervised model (paired data). The model architecture is a residual block based on U-net similar to PG$^2$ ([32]), but extended to get closer to our model. It is extended by applying our mask multiplication operation after the first convolution block for the supervised take-off experiment. Likewise, we add our Fit-in module for the supervised try-on experiment. We present quantitative results on the translation performance of the try-on / take-off tasks in Table 2.
for the FashionStyle dataset with related qualitative results presented in Fig. 6.

**Discussion.** A quick inspection of Table 2 reveals that, based on the LPIPS metric, the full model generates images with the highest similarity to the ground-truth on the try-on task among the unpaired variants. Our full model generates sharper and more consistent results than other models, but does not obtain the highest SSIM. This is also observed in person generation and super-resolution papers [32, 21]. The try-on ROI scores of W/O Fit-in module is not applicable since without the context information, the network cannot determine the target generated shape, i.e. ROI cannot be determined. This task seems to be affected most when the mask attention is dropped. This confirms the relevance of this feature when translating shape from images in this direction (try-on).

For the case of the take-off task, results are completely dominated by the full model among the unpaired variants. However, different from the try-on task, the take-off task is mostly affected by the removal of the perceptual loss (i.e. LPIPS) and Fit-in modules. The Fit-in module is set in the try-on stream, but since the two streams are trained jointly, the take-off stream is indirectly affected by the performance of the try-on stream. Therefore, the take-off result of W/O Fit-in module is the worst. Although this trend is different from the try-on task, it is not surprising given that for the take-off task, the expected shape of the translated image is more constant when compared with that of the try-on task which is directly affected by the person’s pose. Moreover, the output of the take-off task is mostly dominated by uniformly-coloured regions, which is a setting in which
perceptual similarity metrics, such as LPIPS, excel.

A close inspection of Fig. 6 confirms the trends previously observed. Note how the full model produces the most visually-pleasing result; striking a good balance between shape and level of details on the translated items. The other unpaired variants (except W/O Fit-in module) tend to generate blurry results and lose details, e.g. patterns and logos, while maintaining the basic shape and context well. More critical, W/O Fit-in module no longer preserves both shape and loses details. Especially, without context information guidance, it is difficult for the model to learn the one-to-many mapping resulting in inconsistent outputs. We have noted that failures are mostly caused by incorrectly estimated masks and heavy occlusion.

It is remarkable that quantitatively speaking (Table 2), the performance of our method is comparable to that of the supervised model. Moreover, while the supervised model is very good at translating logos, our method still has an edge when translating patterns (e.g. squares from the 1st row and stripes from the 3rd row of Fig. 6), without requiring paired data.

4.2. Clothing try-on / take-off on VITON

We complement the results presented previously with a qualitative experiment (see Fig. 7) on the VITON dataset using the full model. We see that our method is able to effectively translate the shape of the clothing items across the domains. It is notable that on the try-on task, it is able to preserve the texture information of the items even in the presence of occlusions caused by arms. This is handled by the proposed Fit-in module (Sec. 3) which learns how to combine foreground and contextual information.

4.3. Comparisons with existing methods

We compare our model w.r.t. CycleGAN ([46]), MU-NIT ([16]) and VITON ([12]). Fig. 2 shows quali-
Figure 6. The quality results of try-on (left) and take-off (right) tasks. Please note the "GT" in the take-off is just a reference. The whole model is trained by using unpaired data.

Table 3. We do not provide the Try-on ROI scores for the same reason explained in Sec. 4.1. The comparison with the supervised method VI-TON is shown in Fig. 9. It is motivating that even without any supervised paired data, our method achieves competitive results.

4.4. Ablation Study: Components

Given the similarity between MUNIT and our method, we ran a more detailed ablation study, see Table 4, in order to analyze the margin between these two methods. Note that we use our variant of MUNIT, i.e. MUNIT*, where the shape mask is used to segment the features instead of the input image, then each channel dimensions become 1.5 times larger and one more residual block is used in the decoder. We also add an additional component (A) in the analysis. When not sampling the style code (A in Table 4), performance increases significantly. This is an implicit shared style space constraint because there is a style code latent reconstruction loss. When using an explicit shared style encoder (B), the performance increases further. In addition, this also enables to extract the compact feature. Further, the Fit-in module (C) is essential to enable the try-on stream, since it utilizes the context information guidance to enforce the output to be deterministic. In our experiments applying multiple AdaIN (D) proved useful to stabilize the training process. The mask attention (E) and perceptual loss (F) further improve the performance. Finally, we verified these observations on top of the original MUNIT where introducing A produces a significant increase in performance (as
Figure 7. Try-on and take-off results on the VITON dataset. For try-on (top) each column shows a person (from the top row) virtually trying on different clothing items. For take-off (bottom) each example consists of three images: input image, generated take-off image and the ground-truth (GT) image. Zoom in for more details.

Figure 8. Clothing retrieval ablation study. Note that relevant factors for the retrieval are somewhat the opposite of those from the translation task.

Table 3. Comparisons w.r.t. state-of-the-art methods on Fashion-Style.

| Method               | Take off (SSIM/LPIPS-VGG) |
|----------------------|---------------------------|
| CycleGAN             | 45.63 / 47.47             |
| MUNIT                | 45.97 / 46.53             |
| MUNIT, shared S.E.   | 50.44 / 49.15             |
| Ours                 | 61.19 / 34.37             |

also noted in [16]), with a further boost when considering B. Note that MUNIT*+A B produces blurry images, leading to high SSIM scores [21]

4.5. Clothing retrieval

We present the in-shop clothing retrieval results using the extracted style features. We apply the shared style encoder as feature extractor to extract the style codes and then use L2 distance to measure the similarity for retrieval.

Figure 9. Comparison with VITON (supervised) [12] on the try-on task.

Table 4. Mean SSIM and LPIPS-VGG similarity when considering the following components: A: Use the encoded style code of the input image instead of sampling from the style latent space. B: Shared style encoder. C: Fit-in module. D: Apply AdaIN to the convolutional layers in both Residual and Up-sampling blocks. E: Mask attention. F: Perceptual loss.

| Method | Try-on ROI (SSIM/LPIPS) | Take off (SSIM/LPIPS) |
|--------|------------------------|-----------------------|
| MUNIT* | N/A 55.65 / 43.88      |                       |
| MUNIT* + A | N/A 58.45 / 37.93        |                       |
| MUNIT* + A B | N/A 58.98 / 36.24       |                       |
| MUNIT* + A B C | 68.09 / 27.65        | 55.90 / 38.74            |
| MUNIT* + A B C D E | 66.78 / 27.37        | 58.96 / 36.62            |
| MUNIT* + A B C D E F | 66.42 / 27.02        | 61.19 / 34.37            |
| MUNIT | N/A 51.92 / 48.16      |                       |
| MUNIT + A | N/A 54.03 / 44.18        |                       |
| MUNIT + A + B | N/A 55.59 / 43.83        |                       |

Protocol. The shared style encoder is trained and tested on the FashionStyle training and testing sets, respectively. During retrieval, there are 1,302 query images and 434 database images. The query images are all from domain A, i.e. clothed people, and database images from domain B, i.e. our individual clothing items. For fair comparison, we apply the clothing masks to the query input of both our method and other methods. As shown in Table 5, we provide four baselines: Color histogram, Autoencoder+GAN (AE+GAN), ResNet-50/152 ([13]) and FashionNet ([30]). Following [19]'s work, we only use the triplet branch of FashionNet. In addition, for the comparison purpose, we use 8 dimensions and 128 dimensions feature by adding one more fully connected layer after the original one. For AE+GAN, the latent code of the AE is 128-dimension. We train the model using both domain A and domain B images.
ResNet-50 and ResNet-152 are trained from ImageNet.

**Discussion.** Our method outperforms all the baselines except LPIPS-Alex and FashionNet. It is noted that LPIPS-Alex extracts the feature maps of different layers as clothing features, resulting in a very high dimensional feature vector (≈640K dimensions). This costs a lot, both in compute time as well as in storage costs, which both scale linearly with the dimensionality. FashionNet is trained in a supervised way and uses a triplet loss. It is not surprising that its results are better than ours. Our extracted style code on the other hand has a very low dimension (e.g., 8), which can significantly reduce (over 80K times) the computation. Furthermore, combining our method with LPIPS-Alex in a simple coarse-to-fine way, i.e., first using our method to quickly obtain the coarse top-k results and then using LPIPS-Alex to re-rank these results, can achieve the best performance among the unpaired methods while reducing the aforementioned costs significantly. The k value can be selected as the point where the performance of our method and LPIPS gets close, e.g., k=20k=5 for Ours (SD=8/SD=128), or adapted based on user requirements. A similar gain in performance can be achieved for the case of the VITON dataset (Table 6).

In addition, we provide a clothing retrieval ablation study on FashionStyle, as shown in Fig. 8. It is interesting to observe that the performance of the retrieval process is affected by different factors than that of the image translation process (Sec. 4.1). We hypothesize that the translation task directly exploits shape related components in order to achieve detailed image generation. On the contrary, the retrieval task considers representative features regardless of whether they grant accurate shape transfer.

We also provide the computation complexity analysis for the retrieval. We use Euclidean distance to measure the difference between the features extracted from two different images. For each query, computation complexity is $O(d \cdot n)$ which scales linearly with the feature dimension d and the number of database images n. Thus, the computation complexity of our method is 80k times ($SD=8$) or 5k times ($SD=128$) smaller than LPIPS-Alex according to the dimension in Table 5. As to LPIPS-Alex+Ours, the computation complexity is $O(d_{Ours} \cdot n + d_{LPIPS} \cdot k), k \ll n$ which maintains the performance and significantly reduces the computation compared to $O(d_{LPIPS} \cdot n), d_{Ours} \ll d_{LPIPS}$ for our naive implementation. While more efficient retrieval algorithms exist, the dependence on the feature dimensionality remains.

**4.6. Face shape transfer**

We conduct experiments related to face translation. In the first experiment, given the input face and the target context (body), we generate a new image where the input face is fitted on the target context (try-on task). In the second experiment, we perform a face take-off task where given a face image with a side viewpoint, we generate an image where the face from the input is rotated towards the front and zoomed-in. We conduct these experiments on the
CMU MultiPIE dataset. Qualitative results are presented in Fig. 11. We present translation similarity measurements in Table 7.

**Discussion**

As can be noted in Fig. 11, images from the different domains, i.e. frontal and side view faces, exhibit many differences regarding to scale and the presence of other parts of the body. Yet, the proposed method is able to achieve both translation tasks with a decent level of success. Fig. 11 shows that, for both tasks, apart from facial orientation features such as facial hair, lip color, accessories, and skin color are to some level properly translated. It is remarkable that this has been achieved without using facial landmarks like eyes, nose, mouth, ears, as in existing work ([14, 44]). Failures are mainly caused by incorrectly estimated masks, large pose variation, and inconsistent skin colors². Table 7 shows that the proposed method has a comparable performance on both faces and clothing related datasets.

**5. Conclusion**

We present a method to translate the shape of an object across different domains. Extensive empirical evidence suggests that our method has comparable performance on both faces and clothing data. Moreover, our ablation study shows that the proposed mask attention and Fit-in module assist the translation of shape, thus, improving the generation process. Finally, we have shown that the features learned by the model have the potential to be employed for retrieval tasks, in spite of their low dimensionality.
