Flavobacterium columnare is a bacterial pathogen causing high mortality rates for many freshwater fish species. Fish vaccination with a safe and effective vaccine is a potential approach for prevention and control of fish disease. Here, in order to produce bacterial ghost vaccine, a specific Flavobacterium lysis plasmid pBV-E-cat was constructed by cloning PhiX174 lysis gene E and the cat gene with the promoter of F. columnare into the prokaryotic expression vector pBV220. The plasmid was successfully electroporated into the strain F. columnare G4cpN22 after curing of its endogenous plasmid. F. columnare G4cpN22 ghosts (FCGs) were generated for the first time by gene E-mediated lysis, and the vaccine potential of FCG was investigated in grass carp (Ctenopharyngodon idellus) by intraperitoneal route. Fish immunized with FCG showed significantly higher serum agglutination titers and bactericidal activity than fish immunized with FKC or PBS. Most importantly, after challenge with the parent strain G4, the relative percent survival (RPS) of fish in FCG group (70.9%) was significantly higher than FKC group (41.9%). These results showed that FCG could confer immune protection against F. columnare infection. As a nonliving whole cell envelope preparation, FCG may provide an ideal alternative to pathogen-based vaccines against columnaris in aquaculture.

1. Introduction

Flavobacterium columnare, a Gram-negative-gliding bacterium, is the causative agent of columnaris disease, one of the most important bacterial diseases of freshwater fish species [1]. This bacterium is ubiquitous in aquatic environments, affecting wild and cultured fish as well as ornamental fish in aquaria [2]. The onset of columnaris disease is characterized by external infections in the fish body surface, gills, or fins. The disease often ends in death, leading to large economic losses in the fish farming industry.

In recent years, control of fish diseases using chemotherapy results in emergence of antibiotic-resistant microbes and negative impacts on environment and human beings [3–6]. Therefore, vaccination has become an increasingly important prevention strategy against infectious agents in farmed fishes [7]. Several attempts have been made to induce protection against columnaris disease with formalin- or heat-inactivated preparations of F. columnare, yet no protection or only partial protection was achieved following immersion or injection immunization [8–10]. Currently, a modified live columnaris vaccine has been developed and commercialized in the United States [11], and it is efficacious for prevention of columnaris disease in channel catfish and largemouth bass fry [12, 13]. However, live vaccines may bear the danger of reversion.

Bacterial ghosts have been given increasing attention as a promising new approach in nonliving vaccine technology. The potential usefulness of the technology has been reported in a wide variety of mammalian pathogenic Gram-negative bacteria [14–16] and in a fish pathogenic bacterium, Edwardsiella tarda [17, 18]. Generally, Bacterial ghosts are produced by the controlled expression of bacteriophage PhiX174 lysis gene E, and the E protein leads to the formation of small...
transmembrane pores through which cyttoplasmic contents are expelled [14–19]. The resultant bacterial ghosts retain the functional and antigenic determinants of the envelope with their living counterparts; therefore they possess good immunogenicity and bioadhesive properties and are able to induce effective immunoprotection [20, 21].

In this study, F. columnare ghosts have been generated for the first time by gene E-mediated lysis, and immune protection against infection of F. columnare was detected in Grass carp (Ctenopharyngodon idellus) by intraperitoneal immunization with the ghosts.

2. Materials and Methods

2.1. Bacterial Strains, Culture Conditions, and Plasmids. The highly virulent pathogenic strain Flavobacterium columnare G4, isolated from a severe natural outbreak of gill rot disease in cultured cyprinid fishes, was kindly provided by Institute of Hydrobiology, Chinese Academy of Sciences. The strain was identified by biochemical diagnostic methods [22] and species-specific PCR [23]. It is resistant to ampicillin and tobramycin but highly sensitive to chloramphenicol. Shieh et al. [24] reported the first detection of the cat gene in F. columnare G4 with the pPFu DNA polymerase (Fermentas) which produces blunt ended PCR products and primers Catpro-F (5′-GATAGATAGAAAAAGATAAGTA-3′) and Catpro-R (5′-GCGATTGCTCTTTTTTATAAAAT-3′). The primers were designed according to the upstream sequence of acetyl-coenzyme, a synthetase gene of F. columnare in Genbank (AY387595.2). The DNA fragment including the promoter and cat gene was amplified from pT-pro-cat with the Pfu DNA polymerase (Fermentas) and ligated into plasmid pBV-E which was predigested with ScaI. The resulting plasmid was designated as pBV-E-cat (Figure 1).

2.2. Construction of Gene E-Mediated Lysis Vector with Cat Gene. The lysis gene E was amplified by PCR from PhiX174 RF1 DNA which was purchased from Fermentas.

2.3. Curing of an Endogenous Plasmid from F. columnare G4. F. columnare G4 was cured of its endogenous plasmid by use of the intercalating dye acridine orange (AO, Sigma, USA). Basically, the filter-sterilized AO was added into the logarithmically growing culture (Tobramycin 1 μg/mL, OD<sub>600</sub> = 0.4) of F. columnare G4 at concentrations ranging from 25 μg/mL to 450 μg/mL in 18 groups. The culture was incubated at the optimum growth temperature 26°C for 26 h. Then the culture containing the highest concentration of AO which still allows growth was used as a source of inoculum for plating cells on Shieh agar plate at 26°C until colony growth. Individual colonies were detected by plasmid purification and identified by primer-specific PCR with primers Fcp510-F (5′-GGCGATTTGCCTTTTTATAAAAT-3′), Fcp1152-F (5′-GGTTCGGCG-TTCTATGG-3′), and Fcp1152-R (5′-GGTGGTGAGTCGGTATGGTCTCCTTCTGTG-3′) according to the sequence of the plasmid (Another study processing). After large-scale screening, 28 strains which have stably lost the endogenous plasmid were obtained and designated as F. columnare G4cpN1-N28.

2.4. Electroporation of F. columnare G4cpN1-N28 and Generation of F. columnare G4cpN22 Ghosts. The above strains were inoculated into 100 mL Shieh broth and grown at 26°C to an OD<sub>600</sub> of 0.3 with agitation of 150 rpm. The cells were washed in ice-cold sucrose electroporation buffer (137 mM sucrose, 1 mM Hepes, 10% (v/v) glycerol, pH 8.0) and then suspended in ice-cold sucrose buffer at 1/100 of the original volume. The lysis plasmid pBV-E-cat DNA (3-4 μg) was mixed with 100 μL of the cell suspension, transferred to a precooling 1 mm cuvette and electroporated using a Gene Pulser (Bio-Rad, CA, USA) and Pulse controller (1.5 kV, 25 μF, 200 Ω) producing a time constant of ±0.4 ms. Immediately after electroporation, 800 μL of Shieh medium was added to cells and incubated for 1 h at 26°C. After incubation,
cells were plated onto Shieh agar plates containing 10 μg/mL chloramphenicol and grown at 26°C for 24–36 h.

*F. columnare* G4cpN22 was the only one strain which had the ability to accept and maintain the pBV-E-cat. When the cultures reached an OD$_{600}$ of 0.3 at 26°C, the expression of the gene $E$ was induced by a temperature upshift to 42°C immediately. The number of cells was determined using a 6 × 6 drop plate method [25] before induction, with the exception that Shieh agar plates were used and incubated at 26°C for 36 h. At different time points after induction, an optical density was measured until no further decrease was detected, and viable cell counts were determined by plating serial dilutions on Shieh agar plates. At the end of the lysis process, 100 μL of cultures was inoculated on Shieh agar plate in order to examine whether or not there were any surviving cells. Efficiency of ghost induction was expressed by lysis rate which was calculated using the following formula: lysis rate = (1 − CFU of lysis completed/CFU before induction) × 100%. Finally, the harvested *F. columnare* G4cpN22 ghosts (FCGs) were washed twice with ice-cold phosphate-buffered saline (PBS, pH 7.3), lyophilized, and stored at 4°C until further use. The lyophilized FCG preparations were reconstituted with PBS to a bacterial concentration of 1 × 10$^8$ cells/mL prior to immunization.

2.6. Experimental Fish Immunization and Challenge Test

2.6.1. Fish and Rearing Conditions. Healthy grass carps weighing 45 ± 5 g were obtained from Freshwater Fishery Research Institute of Shandong Province, China. Prior to vaccination, fish were acclimated for at least two weeks in 400 L aquarium supplied with specific pathogen-free aerated fresh water treated with ultraviolet light. Light cycle was held constant at 12 h light/12 h dark per day and water temperature was maintained at 24 ± 2°C. Fish were fed with a commercial pelleted diet at 2% body weight per day throughout the study. Fish were anaesthetized by immersion into 90 mg/L tricaine methanesulfonate (MS-222, Sigma, USA) prior to experiments involving injection, blood collection, or sacrifice. Before each of the infection and vaccination experiments, fish were randomly sampled for the examination of bacterial recovery from blood, liver, and spleen, and no bacteria could be detected in all the fish examined.

2.6.2. Generation of Formalin-Killed *F. columnare*. *F. columnare* G4 was inoculated into Shieh broth and incubated at 26°C for 24 h. For formalin-killed *F. columnare* (FKC) preparation, formalin was added to the culture at a final concentration of 0.3%. After a 24 h incubation at 26°C, bacteria were washed three times with PBS and resuspended in 0.1 M PBS before microscopy.

**Figure 1:** Physical map of the lysis plasmid pBV E-cat. Gene $E$, under transcriptional control of the temperature-sensitive repressor; $rrBT1T2$: ribosome $rrnB$ gene providing translation stop signal terminator sequence; pro: the regulating sequence including promoter; cat: chloramphenicol acetyl transferase gene; ori: replication origin; cIts857: restraining gene of lambda bacteriophage adapted to heat induced expression.

2.5. Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM). The FCGs for SEM were fixed with 2.5% glutaraldehyde in 0.01 M PBS (pH 7.0) at 4°C for 2 h. Cells were rinsed 3 times with the same buffer and postfixed in 1% osmium tetroxide for 1.5 h at 4°C. Subsequently, the cells were dehydrated with a graded series of ethyl alcohol and isoamyl acetate. Following final dehydration, cells were dried with liquid carbon dioxide and sputtered with platinum tetroxide using a pure platinum coater before scanning.

Ghost preparations for TEM (H-800, Hitachi) were obtained the same way, except that fixation was done for 3 h. Then the samples were washed as above and fixed with 2% osmic acid for 2 h, followed by washing three times with 0.1 M PBS before microscopy.
in PBS to a bacterial concentration of $1 \times 10^6$ cells/mL. A viability test of 1% of the resulting volume was conducted on Shieh solid medium and determined to be culture negative. FKC preparation was frozen at $-20^\circ$C until use.

2.6.3. Injection Immunization. Grass carp were divided randomly into three treatment groups, each group with one hundred and sixty fish. Fish in two vaccinated groups were injected intraperitoneally (ip) with 100 $\mu$L of FCG or FKC at $1 \times 10^5$ cells/fish using 27-gauge needles. Fish in the control group were injected ip with 100 $\mu$L of PBS as a mock immunization. At 4 weeks postprimary immunization, identical booster immunizations were administered in the vaccinated groups and fish in the control group were injected ip with 100 $\mu$L of PBS. Before vaccination, blood was collected by caudal venipuncture and pooled from a random sample of ten fish per group to confirm that the fish were free from *F. columnare* antibody.

2.6.4. Serum Agglutination Reaction and Bactericidal Activity Assay. At each time point of postimmunization, serum was collected from 30 randomly selected fish (ten pools of 3 fish) in each group. Serum agglutination reaction was applied to reflect the titres of anti-*F. columnare* antibody produced by grass carp [26]. *F. columnare* G4 was incubated in Shieh broth to midlogarithmic phase and resuspended in PBS. Serial twofold dilution of test serum in PBS and equal volume of *F. columnare* G4 suspension was added to each well of 96-well microtitre plates. Doubling dilutions of positive and negative sera were included on every plate as controls. The plates were covered and incubated in humidified air at 25$^\circ$C for 1 h. The highest serum dilution that showed a circular diffuse button of viable bacteria after serum treatment/the number of viable bacteria after PBS treatment) $\times$ 100%.

2.6.5. Challenge Infection and Immune Protection. Before challenge, all fish were clinically healthy, and there was no evidence of *F. columnare* infection. A random sample of 120 fish was selected from each group (control group and both vaccinated groups) and divided into three replicate of 40 fish at time of challenge. The fish were challenged at day 50 postprimary immunization, via ip injection with *F. columnare* G4 at $2 \times 10^6$ cells/fish ($5 \times LD_{50}$ based on preliminary work). Mortality was monitored twice daily for 14 days following challenge, and the cumulative percent mortality (CPM) was calculated for each treatment group. Relative percent survival (RPS) was determined as previously described [28], RPS = (1 – immunized group mortality/control group mortality) $\times$ 100. Dead or moribund fish exhibited gross pathological changes, and routine bacteriological examination was performed on freshly dead fish.

2.7. Statistical Analysis. All data were presented as mean ± SD. Statistical analyses were performed using SPSS 15.0 software (SPSS Inc., Chicago, IL, USA). Serum agglutination titres and bactericidal activities were analyzed by two-way ANOVA followed by pairwise comparisons (Tukey’s test). Challenge test data were analyzed by Chi-square test. Differences were considered significant at $P < 0.05$.

3. Results

3.1. Generation and Characterization of *F. columnare* G4cpN22 Ghost. Since *F. columnare* G4cpN22 was high sensitive to chloramphenicol, but not to ampicillin, a specific lysis vector with the cat gene had to be constructed (Figure 1). The lysis plasmid pbV E cat was successfully electroporated into *F. columnare* G4cpN22 which growth characteristics were similar to *F. columnare* G4. Generation of *F. columnare* ghosts (FCGs) was performed by shifting the incubation temperature to 42$^\circ$C to inactivate the repressor protein and activate lysis gene E. Onset of the lysis occurred 1 h after temperature elevation because the numbers of viable cells began to decrease at 1 h after induction, and the lysis process was completed 10 h after induction (Figure 2). The results of three replicate experiments showed the efficiency of FCGs induction was 99.99% at the end of the lysis process. The lyophilized FCGs were analyzed for survivors by inoculating 100 mL of growth media with a tenfold immunization dose at 26$^\circ$C, but no bacterial growth was detected. The lyophilized FCG preparation was used for vaccination studies in fish.

Electron microscopic analysis of FCG revealed no gross alterations in cellular morphology compared to unlysed cells (Figures 3(a) and 3(b)) except for the lysis pore (arrow, Figure 3(a)). Pores ranging from 100 to 300 nm in diameter were observed in FCG by scanning electron microscopy. The structural integrity and the loss of cytoplasmic materials were observed in FCG by transmission electron microscopy (Figure 3(b)).

3.2. Serum Agglutination Reaction and Bactericidal Activity Assay. The agglutination reaction against *F. columnare* G4 was detected in grass carp immunized ip with bacterial ghosts, formalin-killed cells, or PBS. Fish immunized with FCG or FKC showed significantly higher agglutination titer than control fish in which no agglutination reaction was detected, while fish immunized with FCG showed significantly higher titers than fish immunized with FKC at all the examined time points ($P < 0.01$) (Figure 4). The agglutination reaction in FCG group initially peaked at 2 weeks postprimary immunization, subsided by week 4 and then more than doubled (mean geometric titre 478) 2 weeks
after booster immunization (6 weeks). The high titer of FCG group was 3.5-fold higher than FKC group and persisted longer than FKC group.

Serum bactericidal activity was the lowest in PBS group and the highest in FCG group. Serum bactericidal activity of FCG group was elevated significantly above FKC group and PBS control group at all times postimmunization \((P < 0.01)\) (Figure 5). The viable bacterial counts (41%) were closely 2-fold lower in FCG group compared with FKC group (80%) at 2 weeks after booster immunization (6 weeks).

**3.3. Induction of Protective Immunity following Immunization with FCG Vaccine.** A protective immune response against virulent *F. columnare* G4 was conferred to grass carp following immunization by ip injection with FCG preparation (Table 1). Fish given mock immunizations with PBS sustained high CPM (nearly 100%) upon challenge with the *F. columnare* G4 strain, while fish immunized with FCG or FKC exhibited a significantly decreased CPM at 7 weeks post-primary immunization \((P < 0.05)\). The RPS of FCG group was 70.9%, significantly higher than the RPS of FKC group (41.9%). Challenge mortalities exhibited typical signs of *F. columnare* infection. Bacteria with phenotypic characteristics of *F. columnare* G4 were recovered from all dead fish.

**4. Discussion**

Bacterial ghosts represent a potential new concept in genetically inactivated vaccines. In the present study, *F. columnare* ghosts were generated for the first time by the controlled expression of the lysis gene *E*. Gene *E*-mediated lysis of bacteria resulting in empty cell envelopes is suggested as an alternative approach for the inactivation of bacteria without chemical or physical stress, which have frequently caused the reduction of antigenicity [8–10]. Since the outer membrane proteins (OMPs) of pathogenic bacteria play important roles in protective antigenicity [29–31], the minimized conformational changes of OMPs in bacterial ghosts would provide a promising avenue for enhancing vaccine efficacy.

However, the lysis process of *F. columnare* G4cpN22 harboring plasmid pBV-E-cat was slower than many other Gram-negative bacteria such as *E. coli*, *Salmonella enteritidis*, and *Vibrio cholerae*, in which lysis was completed 2–4 h after lysis induction [32, 33]. Previous studies proved that the promoters which drive gene expression in other gram-negative bacteria generally do not function well in the Bacteroidetes including *Flavobacterium* species [34, 35]. It was speculated that the slower lysis behavior observed in *F. columnare* might result from reduced power of the lambda PR/PL promoter in *F. columnare*, reduced susceptibility of the *F. columnare* cell wall to the E protein, or lower copy of plasmid pBV-E-cat in *F. columnare*. Further study to quantify the gene *E* expression during lysis induction would be valuable to find the factor responsible for the weakened lysis kinetics.

The immune response and protection induced after immunization of grass carp with FCG vaccine were first tested. It was found that fish immunized with FCG through ip injection showed significantly higher serum agglutination titers and serum bactericidal activity than fish immunized with FKC, which indicated that FCG was more favorable to induce specific humoral immune responses. An elevated level of protection in FCG vaccinated fish to the ip injection challenge was also observed, which is consistent with previous findings [18, 36]. The low level of response to FKC preparations could be related to the inactivation of major immunogenic proteins. Bader et al. [9] reported that formalin inactivation resulted in masking of at least one potentially important *F. columnare* antigen in channel catfish. The effect of formalin on the antigenic properties of *F. columnare* was partially addressed here by killing the bacteria with a low formalin concentration (0.3%) and washing three times in PBS. Nevertheless, the protein cross-linking properties of formalin may have resulted in reduced antigenicity. Compared to formalin-killed bacterial vaccines, the adjuvant effect of ghost bacterial vaccines has been reported in many pathogenic bacteria [20]. Bacterial ghosts carry immunostimulatory compounds that have adjuvant properties, such as lipopolysaccharides (LPS), lipids, peptidoglycan, or flagella. These intrinsic adjuvant properties of bacterial ghosts were shown to activate the innate immune system as well as the acquired immune response [37, 38]. Moreover, some reports showed effective induction of cell-mediated immunity, which would play a key role in protection against intracellular pathogens, by bacterial ghost vaccines [39–41].

In conclusion, FCGs have been shown to induce stronger protective immunity than FKC in grass carp. Given its
Figure 3: Electron microscopy analyses of *F. columnare* G4cpN22 ghosts. (a) Arrow showed the transmembrane lysis tunnel located mainly at the cell poles via SEM. (b) Loss of cytoplasmic materials of *F. columnare* G4cpN22 ghosts was shown by TEM. The lysed cells showed uneven and low electron density and retained the basic cell morphology of the bacterial cells, while the unlysed cells showed even and high electron density in an integral cell structure.

Table 1: Cumulative percent mortality (CPM) and relative percent survival (RPS) of grass carp following *F. columnare* G4 strain challenge at 50 days after primary immunization.

| group | Number of fish challenged | Mean CPM ± SD (%) | RPS (%) |
|-------|---------------------------|-------------------|--------|
| FCG   | 120                       | 28.3 ± 5.0<sup>a</sup> | 70.9   |
| FKC   | 120                       | 56.7 ± 8.0<sup>b</sup> | 41.9   |
| PBS   | 120                       | 97.5 ± 2.5<sup>c</sup> |        |

FCG, *F. columnare* G4cpN22 ghosts; FKC, formalin-killed cells. Values with different superscripts indicate a significant difference at *P* < 0.05.

Figure 4: Serum agglutination titres of fish vaccinated with FCG and FKC at different time points post-primary immunization. Grass carp were vaccinated with FCG or FKC via intraperitoneal injection with a boost at 4 weeks after primary immunization. Serum agglutination titres represent the highest dilutions that gave rise to positive reaction. The titres of FCG group were significantly higher than FKC group at all the examined time points (*P* < 0.01).

Figure 5: Serum bactericidal activities of grass carp vaccinated with FCG or FKC. The grass carp were vaccinated with FCG or FKC via intraperitoneal injection with a boost at 4 weeks after primary immunization. Serum bactericidal activities of FCG group were significantly higher than FKC group at the examined time points of post-immunization (*P* < 0.01).
safety and high level of immunoprotective efficacy, FCG may provide an ideal alternative to pathogen-based vaccines against columnaris in aquaculture.
