Large low field magnetocaloric effect in first-order phase transition compound \(\text{TlFe}_3\text{Te}_3\) with low-level hysteresis

Qianhui Mao\(^1\), Jinhu Yang\(^2\), Hangdong Wang\(^1,2\), Rajwali Khan\(^1\), Jianhua Du\(^1\), Yuxing Zhou\(^1\), Binjie Xu\(^1\), Qin Chen\(^1\) & Minghu Fang\(^1,3\)

Magnetic refrigeration based on the magnetocaloric effect (MCE) is an environment-friendly, high-efficiency technology. It has been believed that a large MCE can be realized in the materials with a first-order magnetic transition (FOMT). Here, we found that \(\text{TlFe}_3\text{Te}_3\) is a ferromagnetic metal with a first-order magnetic transition occurring at Curie temperature \(T_C = 220\text{ K}\). The maximum values of magnetic entropy change (\(\Delta S_M^\text{max}\)) along the crystallographic c-axis, estimated from the magnetization data, reach to \(5.9\text{ J kg}^{-1}\text{ K}^{-1}\) and \(7.0\text{ J kg}^{-1}\text{ K}^{-1}\) for the magnetic field changes, \(\Delta H = 0\text{–}1\text{ T}\) and \(0\text{–}2\text{ T}\), respectively, which is significantly larger than that of MCE materials with a second-order magnetic transition (SOMT). Besides the large \(\Delta S_M\), the low-level both thermal and field hysteresis make \(\text{TlFe}_3\text{Te}_3\) compound an attractive candidate for magnetic refrigeration. Our findings should inspire the exploration of high performance new MCE materials.

Magnetic refrigeration based on MCE is an environment-friendly, high-efficiency technology compared to the traditional gas-cycle refrigeration\(^1\text{–}^4\). After the discovery of the first magnetic refrigeration prototype near room temperature\(^5\) and the giant MCE in \(\text{Gd}_5(\text{Si}_{2}\text{Ge}_2)\)\(^6,7\), a large MCE has been realized in a lot of materials in the past two decades, such as \(\text{ReCo}_2\) (Re = Er, Ho, and Dy) alloys\(^8,9\), manganite oxides (Re, M)\(\text{MnO}_3\) (Re = Lanthanide, M = Ca, Sr, and Ba)\(^10,11\), Ni-Mn-X (X = Ga, In, and Sn) based Heusler alloys\(^12,16\), MnAs based compounds\(^3,17,19\), \(\text{La(Fe, Si)}_{13}\) and related compounds\(^18,20\), as well as rare earth based intermetallic compounds\(^24\)\text{–}30\). Amongst the families of MCE materials, the compounds with first-order magnetic transition (FOMT) have been found promising due to their large and/or sharp changes in magnetization and the strong coupling between crystallographic structure and magnetism, such as \(\text{Gd}_5\text{Ge}_4\)\(^{1,7}\), \(\text{MnAs}\)\(^{1,18,31}\), \(\text{MnFe(As, P, Si, Ge)}\)\(^{17,32}\), \(\text{LaFe}_{13-x}\text{Si}_x(H_2)\)\(^{14,21,23}\) and Heusler-type magnetic shape-memory alloys\(^{14,18}\). However, in these materials, the magnetic transitions are frequently accompanied by significant thermal and/or magnetic hysteresis, which would limit the life span of refrigerants or even make the refrigeration cycle impossible\(^5,33\). In order to reduce or even eliminate the magnetic hysteresis losses, there have been two strategies. One is to treat the giant MCE materials by special methods, such as microstructure-tuning, as porosity\(^34\), fragmentation\(^35\)\text{–}37, melt-spun\(^38\)\text{–}40, or chemical tuning, as doping\(^41\). Another is to search for new high performance compounds with SOMT\(^32\). However, the performances in materials with SOMT are rather modest when compared with that with FOMT. It is therefore interesting to search for new FOMT materials with low-level hysteresis and without any additional treatments.

The crystal structure and physical properties of \(\text{TlFe}_3\text{Te}_3\) were reported by two groups in 1984\(^43,44\). \(\text{TlFe}_3\text{Te}_3\) crystallizes in a hexagonal structure with space group \(P6_3/m\), which consists of one-dimensional metallic cluster \([\text{Fe}_3\text{Te}_3]_\text{c}\) chains along the hexagonal c-axis, separated by the parallel chains of Tl atoms (see Fig. 1). The authors concluded that the compound undergoes a first-order transition from paramagnetic to ferromagnetic at 220 K based on their physical property measurements. However, neither of them observed discernible thermal and field hysteresis. Since the absence of hysteresis is appealing for magnetic refrigerant, in this report, we recheck the type of the magnetic transition and elucidate the MCE of \(\text{TlFe}_3\text{Te}_3\) by performing resistivity and magnetization...
measurements. We found that this compound exhibits a large MCE with a small magnetic field change, $\Delta H$, and with a low-level thermal and field hysteresis, thus identifying it to be another class of solids for the magnetic refrigerants.

**Results and Discussion**

Figure 1 presents the powder x-ray diffraction (XRD) pattern of TlFe$_3$Te$_3$ and its Rietveld refinement. All the diffraction peaks could be indexed by a hexagonal structure with space group P6$_3$/m. The lattice parameters $a = 9.355(1)$ Å and $c = 4.224(5)$ Å were obtained by the refinement, which are in good agreement with previous reports $^{44}$. The electron probe micro-analyzer (EPMA) experiments performed on several single crystals verified that the sample composition (the average atomic ratio) is of Tl : Fe : Te $= 9.355(1) : 2.95(2) : 3.00(1)$, which is consistent with the nominal composition. The temperature dependence of electrical resistivity along $c$-axis, $\rho(T)$, for a TlFe$_3$Te$_3$ crystal is shown in Fig. 2(a). In the whole measuring temperature range, the positive resistivity-temperature coefficient of $\rho(T)$ indicates its metallic behavior. The resistivity has a very sharp drop at 220 K with detectable thermal hysteresis [see the inset of Fig. 2(a)], which is associated with the first-order ferromagnetic transition. The resistivity at 300 K and 1.8 K are of 120 $\mu\Omega$ cm and 1.8 $\mu\Omega$ cm, respectively. The small resistivity should be viewed as a merit since a good thermal conductivity is required for a high performance magnetic refrigerant material$^{45}$. Both a rather low residual resistivity and a considerable large residual resistivity ratio (RRR) $= 67$ indicate that our crystals are of high quality.

Figure 2(b) shows the magnetization as a function of temperature, $M(T)$, measured from 2 to 300 K in an applied magnetic field $H = 1000$ Oe, aligned both $||$ and $\perp$ the $c$-axis, with a field cooling process. A sharp increase of $M$ for both directions at the Curie temperature, $T_C \approx 220$ K, confirms the occurrence of a ferromagnetic transition. Larger magnetization along $c$-axis suggests that the easy axis of magnetization is in the $c$ axis. As discussed by Uhl et al.$^{43}$ and Pelizzo$^{44}$, the strong magnetic anisotropy observed in the ferromagnetic state is certainly related to its peculiar structure being composed of [Fe$_3$Te$_6$]$_{\infty}$ chains, whose central part is a column of edge-sharing octahedral Fe clusters. The Fe-Fe distance of 2.6 Å within the clusters are comparable to the interatomic distance in metallic iron, while the nearest two Fe atoms belong to different [Fe$_3$Te$_6$]$_{\infty}$ chains are 6.7 Å apart. Thus, a strong anisotropy of the exchange coupling is to be expected. As shown in Fig. 2(c,d), it is clear that the $M(T)$ curves near $T_C$ exhibit a small thermal hysteresis for both directions, which is in contrast to that reported by Uhl et al.$^{43}$ and Pelizzo$^{44}$, who did not observe any hysteresis in their measurements. We observed a distinguishable but very small hysteresis, (i.e., the hysteresis temperature $\Delta T_{th} = 0.2$ K for $H \parallel c$-axis and 0.1 K for $H \perp c$-axis), which suggests that a first-order ferromagnetic transition occurs at $\approx 220$ K.

In order to further identify the type of the transition and to explore the MCE, we performed the isothermal magnetization measurements near the $T_C$. Figure 3 shows the magnetization as a function of magnetic field, $M(H)$, measured at various temperatures around $T_C$ with both $H \parallel c$-axis and $H \perp c$-axis, and with both increasing and decreasing magnetic field. A small magnetic hysteresis was again observed. The maximum hysteresis is 50 Oe for $H \parallel c$-axis [see Fig. 3(a)], while for $H \perp c$-axis, the hysteresis is rather small and becomes even indiscernible [see Fig. 3(b)]. The $M(H)$ curves for both $H \parallel c$-axis and $H \perp c$-axis exhibit a different behavior, which is associated with the large anisotropy of magnetization discussed above. The $M^2$ versus $H/M$ curves for both directions are shown in Fig. 3(c,d), respectively. According to the Banerjee criterion$^{46}$, the curves at some temperatures have a negative slope and a inflection, which confirms further the occurrence of the first-order ferromagnetic transition around 220 K. The small hysteresis in $M(H)$ curves enables us to use the Maxwell equation to estimate the isothermal magnetic entropy change ($\Delta S_M$). The $\Delta S_M$ is calculated by a formula:

$$\Delta S_M(T, \Delta H) = \sum_{0}^{\max} \frac{M_i - M_{i-1}}{T_i - T_{i-1}} \Delta H$$

\[ (1) \]
which is an approximation of the integral form of the Maxwell equation.

$$\Delta S_M(T, \Delta H) = \int_0^H \left( \frac{\partial M}{\partial T} \right) dH$$  \hspace{1cm} (2)

Figure 4(a,b) present the temperature dependence of $-\Delta S_M$ with the magnetic field changes $\Delta H$ up to 0–5 T, for both $H \parallel c$-axis and $H \perp c$-axis. For $H \parallel c$-axis, the $-\Delta S_M(T)$ curve with $\Delta H=0–1$ T shows a pronounced peak around $T_C$, and a table-like behavior can be observed in the $-\Delta S_M(T)$ curves with $\Delta H=0–2$ T and 0–3 T, i.e., there is a temperature range corresponding to the maximum value of magnetic entropy change, which is beneficial for application. With $\Delta H=0–1$, 0–2, 0–3, and 0–5 T, $-\Delta S_M^{\text{max}}=5.9, 7.0, 8.2, 8.5$ and $8.9$ J/kg K, respectively, which increases continuously with the increasing field change and tends to almost saturate at higher magnetic field change. It is known that a "table-like" behavior and no strong $\Delta H$ dependence of $-\Delta S_M^{\text{max}}$ value are typical behaviors for FOMT materials\(^2,45\). Although $-\Delta S_M^{\text{max}}$ values are smaller than that for some giant MCE materials (see Table 1), these values of TlFe\(_3\)Te\(_3\) are comparable with the most potential magnetic refrigerant materials (see Table 1). For the $H \perp c$-axis case, all the $-\Delta S_M(T)$ curves with different $\Delta H$ values exhibit a peak around $T_C$ without table-like behavior, and the maximum value of magnetic entropy change $-\Delta S_M^{\text{max}}$ is smaller than that for the $H \parallel c$-axis. The anisotropy of MCE may originate from the peculiar magnetic structure, as discussed above.

Another important quality factor of magnetic refrigerant materials is the relative cooling power (RCP) or refrigeration capacity (RC), defined\(^29\) usually as the product of $-\Delta S_M^{\text{max}}$ and the full width at half maximum in the $-\Delta S_M(T)$ curve, as an example, $T_{\text{hot}} - T_{\text{cold}}$ for $\Delta H=0–1$ T in Fig. 4(a). RCP/RC is a measurement of the amount of heat transfer between the cold and hot reservoirs in an ideal refrigeration cycle. Due to the limitation of data measured in our experiments, we only estimated that the RCP values for $\Delta H=0–1, 0–2$ and 0–3 T are of 13, 50, and 74.6 J/kg, respectively. Recently, as a figure of merit for the magnetic refrigerant materials, the dimensionless materials efficiency\(^{47,48}\), $\eta = |Q|/W$, is taken into consideration, where electrical or mechanical work, $W$, is done to drive highly reversible caloric effects in an isothermal body, whose entropy is thus modified such that heat, $Q$, flows to ($Q < 0$) or from ($Q > 0$). Here, we estimated the mass-normalized values of $|W|$ by integrating $-\mu_0 \Delta M H$ from the $M(H)$ data at $T_C$, and evaluated the mass-normalized value of heat $Q$ by integrating $\mu_0 H (\partial M / \partial T)_H$ with respect to $H$ from the $M(H)$ data at $T_C$, which follows from the Maxwell relation.

Figure 2. (a) The temperature dependence of resistivity with a current applied parallel to $c$-axis and the expansion near the transition temperature (inset). (b) The temperature dependence of magnetization, $M(T)$, for both $H \parallel c$-axis and $H \perp c$-axis. The $M(T)$ near the transition temperature for (c) $H \parallel c$-axis, (d) $H \perp c$-axis, the arrows show the cooling and heating process during measurements.
μ_0(∂M/∂T)_M = (∂S/∂H)_T. The materials efficiency η values at T_c was estimated to be of 65.7, 32.0, 23.2, 17.1, and 13.9 for ΔH = 0–1, 0–2, 0–3, 0–4, and 0–5 T, respectively.

As a comparison of MCE properties, we choose several compounds with a similar magnetic transition temperature, T_M, as well as some typical materials with a near room temperature, T_M, focusing on the performance under ΔH = 0–2 T (the maximum magnetic field generated by a permanent magnet is about 2 T). As listed in Table 1, although the − ΔS_M^\text{max} of TIFe_3Te_3 is less than that in the some pronounced materials with FOMT, such as GdSi_2Ge_2, MnFeP_0.45As_0.55, LaFe_11.5Si_1.3 and 20-LaFe_11.5Si_1.43 materials, − ΔS_M^\text{max} of TIFe_3Te_3 is significantly larger.
It was found that TlFe₃Te₃ is a FOMT metal with measurements of its resistivity and magnetization to investigate the nature of the magnetic phase transition and the MCE. The relative large MCE at a low $H$ makes this compound a promising candidate for magnetic refrigeration around 220 K. Further efforts should be done to substitute Tl by other nontoxic elements in order to utilize this type of materials widely.

### Methods

Single crystals of TlFe₃Te₃ were grown using a self-flux method. A mixture with a ratio of Tl:Fe:Te = 1:3:3 was placed in an alumina crucible, sealed in an evacuated quartz tube, heated at 923 K for 5 days. The product was a black powder from which needle-like single crystals with a typical dimension of ~0.4 × 0.4 × 4 mm³ could be isolated. Powder XRD measurements on crushed single crystals were carried out at room temperature on a PANalytical x-ray diffractometer (Model EMPYREAN) with a monochromatic Cu $Kα_1$ radiation to identify the phase purity and the crystal structure. The composition was confirmed by an electron probe micro-analyzer (EPMA) (Jeol JXA-8100). The magnetic measurements were performed on a Quantum Design Magnetic Property Measurement System (SQUID-VSM, MPMS-5) and the resistivity measurements were carried out on a Physical Property Measurement System (PPMS-9).

### Table 1. Comparison of the MCE properties with some representative materials with a similar magnetic transition temperature.

| Sample         | $T_M$ (K) | $-\Delta S_{\text{m}}^{\text{max}}$ (0–2 T) | $\Delta \theta$ (K) | RCP (0–2 T) | $\eta$ (0–2 T) | Transition type | Ref.     |
|----------------|-----------|------------------------------------------|---------------------|-------------|----------------|----------------|----------|
| TlFe₃Te₃       | 220       | 7.02                                     | 0.2                 | 50.4        | 32.0           | FOMT           | This work |

This work was supported by the National Basic Research Program of China (Grant Nos 2016FYA0300402, 2015CB921004, and 2012CB821404), the National Natural Science Foundation of China (Grant Nos 11374261 and 11204059), Zhejiang Provincial Natural Science Foundation of China (Grant No. LQ12A04007) and the Fundamental Research Funds for the Central University of China.

Author Contributions

M.F. and Q.M. designed the study, analyzed the data and wrote the paper. Q.M. synthesized the samples and did the transport measurements with J.Y., H.W. and R.K.; J.D. collected, processed and refined the X-ray data; Y.Z., B.X. and Q.C. did the magnetization measurements. All authors discussed the results and commented on the manuscript.
