1 May 2014

ABSTRACT
The scale-dependent galaxy bias generated by primordial non-Gaussianity (PNG) can be used to detect and constrain deviations from standard single-field inflation. The strongest signal is expected in the local model for PNG, where the amplitude of non-Gaussianity can be expressed by a set of parameters ($f_{\text{NL}}$, $g_{\text{NL}}$, ...). Current observational constraints from galaxy clustering on $f_{\text{NL}}$ and $g_{\text{NL}}$ assume that the others PNG parameters are vanishing. Using two sets of cosmological $N$-body simulations where both $f_{\text{NL}}$ and $g_{\text{NL}}$ are non-zero, we show that this strong assumption generally leads to biased estimates and spurious redshift dependencies of the parameters. Additionally, if the signs of $f_{\text{NL}}$ and $g_{\text{NL}}$ are opposite, the amplitude of the scale-dependent bias is reduced, possibly leading to a false null detection. Finally we show that model selection techniques like the Bayesian evidence can (and should) be used to determine if more than one PNG parameter is required by the data.

1 INTRODUCTION
Standard single-field inflation scenarios predict primordial non-Gaussianity (PNG) can be used to detect and constrain deviations from standard single-field inflation. The strongest signal is expected in the local model for PNG, where the amplitude of non-Gaussianity can be expressed by a set of parameters ($f_{\text{NL}}$, $g_{\text{NL}}$, ...). Current observational constraints from galaxy clustering on $f_{\text{NL}}$ and $g_{\text{NL}}$ assume that the others PNG parameters are vanishing. Using two sets of cosmological $N$-body simulations where both $f_{\text{NL}}$ and $g_{\text{NL}}$ are non-zero, we show that this strong assumption generally leads to biased estimates and spurious redshift dependencies of the parameters. Additionally, if the signs of $f_{\text{NL}}$ and $g_{\text{NL}}$ are opposite, the amplitude of the scale-dependent bias is reduced, possibly leading to a false null detection. Finally we show that model selection techniques like the Bayesian evidence can (and should) be used to determine if more than one PNG parameter is required by the data.

2 SCALE-DEPENDENT BIAS AND PNG
The linear matter density contrast in Fourier space $\delta_m(k)$ follows from the curvature perturbations by

$$\delta_m(k, z) = \alpha(k, z) \Phi(k),$$

with

$$\alpha(k, z) = \frac{2k^2 D(z) T(k)}{3 \Omega_m H_0^2},$$

and recently Xia et al. (2011) reported a possible detection of positive $f_{\text{NL}}$ at the 2σ level. However, these studies all assume that the underlying model for PNG is either purely quadratic ($g_{\text{NL}} = 0$) or purely cubic ($f_{\text{NL}} = 0$). In this Letter, we show that the assumption of a one-parameter model significantly biases the estimation of the PNG parameters when both $f_{\text{NL}}$ and $g_{\text{NL}}$ do not vanish. We also illustrate that model-selection techniques like the Bayes factor are powerful tools to identify the model that best describes the available data. This is particularly interesting in light of the next generation of galaxy and cluster surveys like eROSITA (Predehl et al. 2010), Euclid (Laureijs et al. 2011), or LSST (Ivezic et al. 2008) which are expected to significantly reduce the error bars of PNG parameters (e.g. Pillepich et al. 2012, Giannantonio et al. 2012).

* E-mail: nroth@astro.uni-bonn.de
where \( \Omega_m \) and \( H_0 \) are the current matter-density parameter and Hubble constant, \( T(k) \) is the transfer function, and \( D(z) \) is the growth factor normalised to \((1+z)^{-1}\) during the epoch of matter domination.

Non-linear structures form with time via gravitational instability. Let us denote by \( P_m(k) \) the matter power spectrum and by \( P_{mN}(k) \) the cross spectrum between dark-matter haloes (of a given mass) and mass. On large scales, the relation between \( P_{mN}(k) \) and \( P_m(k) \) is given by

\[
P_{mN}(k) = b_1 f_{NL} g_{NL} + \Delta b(k, f_{NL}, g_{NL}),
\]

where \( b_1 \) is the linear bias parameter (a real-valued constant) and \( \Delta b(k, f_{NL}, g_{NL}) \) is a scale-dependent bias term introduced by PNG. Following the work of Smith, Ferraro & LoVerde (2012) (hereafter SFL12), the latter term can be split up into different contributions (to first order in \( f_{NL} \) and \( g_{NL} \)):

\[
\Delta b(k, f_{NL}, g_{NL}) = \frac{\beta_f f_{NL} + \beta_g g_{NL}}{\alpha(k)}.
\]

Its dependence on \( f_{NL} \) was shown to be (Dalal et al. 2008; Matarrese & Verde 2008; Slosar et al. 2008; Giannantonio & Porciani 2010):

\[
\beta_f = 2 (\nu - 1),
\]

with

\[
\nu \equiv [\delta_c (b_1 - 1) + 1]^{1/2}
\]

where \( \delta_c \) is a parameter set to \( \sim 1.4 \) to fit the clustering properties of friends-of-friends halos in numerical simulations. Note that \( b_1 \) modulates the amplitude of the scale-dependent bias through \( \nu \). Similarly, the dependence on \( g_{NL} \) is (SFL12)

\[
\beta_g = \frac{\kappa_0^{(1)}(M) \left[-0.7 + 1.4(\nu - 1)^2 + 0.6(\nu - 1)^3\right]}{d\log \sigma^{-1}} 
\]

with \( \kappa_0^{(1)} \) the skewness of the mass density field (smoothed on the mass scale \( M \)) in the case of \( f_{NL} = 1 \) and \( \sigma \) the linear rms mass-density fluctuation on the scale \( M \). The skewness and its derivative can be expressed in terms of \( b_1 \) and \( \nu \) (see equations 46 and 47 in SFL12). In brief, PNG of the local type makes the bias of dark-matter haloes scale dependent and proportional to \( k^{-2} \) for \( k \to 0 \). It is therefore conceivable to constrain PNG from measurements of the galaxy power spectrum, provided a model that links galaxies to haloes. However, the \( f_{NL} \) and \( g_{NL} \) contributions to the scale-dependent bias in equations (4) show the same scaling with the wavenumber and it is not possible to measure both parameters from studies of a single population of tracers of the large-scale structure. Given that \( \beta_f \) and \( \beta_g \) display different scaling with halo mass and redshift, this degeneracy can be broken by considering several populations of galaxies, possibly within widely separated redshift bins. Recent studies have accomplished this task by combining a number of observational datasets with simple models where either \( f_{NL} \) or \( g_{NL} \) are set to zero a priori. With the help of numerical simulations, in this Letter we study the effect of these simplifying assumptions on the determination of PNG.

3 SIMULATIONS

We have used GADGET-2 (Springel 2003) to perform two sets of dark-matter-only simulations consisting of four realisations each. Each set corresponds to a different fiducial model of PNG assuming \( f_{NL} = 50 \) and \( g_{NL} = \pm 5 \cdot 10^5 \), in accordance with upper limits obtained from cosmic-microwave-background studies (Komatsu et al. 2011, Velia & Sanz 2011). The other cosmological parameters are chosen in concordance with the WMAP5 analysis (Komatsu et al. 2008): \( \Omega_m = 0.279, \Omega_L = 0.721, \Omega_b = 0.0462, \sigma_8 = 0.817, h = 0.7, n_s = 0.96 \). We follow 1024\(^3\) particles within a cubic box of side \( L = 1200 \ h^{-1} \) Mpc, corresponding to a particle mass of \( 1.247 \cdot 10^4 \ h^{-1} \) M\(_\odot\). The initial conditions are generated at redshift 50 using the Zel’dovich approximation to displace particles from a regular Cartesian grid.

Haloes are selected using a friends-of-friends halo finder with a linking length of 0.2 times the mean interparticle separation. We consider only objects with at least 80 particles, so the halo mass range is \( 10^{10} - 10^{15} \) h\(^{-1}\) M\(_\odot\) \( \leq M_{\text{halo}} \leq 2 \cdot 10^{15} \) h\(^{-1}\) M\(_\odot\) at \( z = 0 \). We use outputs at \( z = \{0, 0.5, 1, 1.5, 2\} \). The scale-dependent bias parameter \( b(k) \) for the haloes is measured from the ratio of the (k-binned) halo-matter cross spectrum and the matter auto spectrum, averaged over the four realisations. We only consider the range \( 0.007 \ h \text{ Mpc}^{-1} \leq k \leq 0.04 \ h \text{ Mpc}^{-1} \) where equation (5) holds as shown in SFL12. The errors on \( b(k) \) are calculated using an estimator derived in the appendix of Smith & LoVerde (2011).

To make sure that equations (5)–(8) (with \( \delta_c = 1.42 \)) can also be applied to our simulations, we fix \( f_{NL} \) and \( g_{NL} \) to the input values and use a standard \( \chi^2 \)-fit to measure \( b_1 \) as a function of halo mass and redshift. We find good \( \chi^2 \) values in all cases, and the fitted \( b_1 \) is compatible with the value expected for the case of Gaussian initial conditions (see equation 14 from Pillepich et al. 2010). We can therefore safely assume that the fitting formulae given by SFL12 accurately describe the scale-dependent bias for our sets of simulations.

4 PARAMETER ESTIMATION

We employ the simulations to build mock observational data for \( b(k) \) and use them to estimate the PNG parameters under different model assumptions. We consider two sets of halo mass and redshift bins as described in Table 1. The first set is chosen to closely resemble the observations used by Xia et al. (2011). The second set covers a wider range in redshift and linear bias parameter \( b_1 \) and exemplifies datasets (for groups and clusters of galaxies) that will be available in
illustrates the properties of specific halo subsamples from our simulated dataset described above: redshift, mass range (in $10^{13} M_\odot$), linear bias parameter $b_1$, number of objects in each mass bin, $N_{\text{halo}}$, after combining the four realisations. We denote this as the “current sample”. The bottom section refers to an hypothetical sample of more massive objects that should become available in the near future. We label this the “future sample”.

The top section describes the galaxy samples used in the analysis of Xia et al. (2011): redshift, type, effective linear bias parameter $b_{\text{eff}}$ and number of objects $N_{\text{gal}}$. The middle section illustrates the properties of specific halo subsamples from our simulations that have been selected to approximate the observational dataset described above: redshift, mass range (in $10^{13} h^{-1} M_\odot$), linear bias parameter $b_1$, number of objects in each mass bin, $N_{\text{halo}}$, after combining the four realisations. We denote this as the “current sample”. The bottom section refers to an hypothetical sample of more massive objects that should become available in the coming times. We label this the “future sample”.

### Table 1

| $z$   | $0$ | $0.5$ | $1$ | $1.5$ | $2$ |
|-------|-----|-------|-----|-------|-----|
| Type  | -   | LRGs  | NVSS| QSOs  | -   |
| $b_{\text{eff}}$ | -   | $1.9$ | $2$ | $2.3$ | -   |
| $N_{\text{gal}}$ | -   | $10 \cdot 10^5$ | $1.4 \cdot 10^5$ | $1.7 \cdot 10^5$ | -   |
| Mass  | -   | $1.6-2.5$ | $1-2.5$ | $1-1.25$ | -   |
| $b_1$ | -   | $1.8$ | $2$ | $2.9$ | -   |
| $N_{\text{halo}}$ | -   | $6 \cdot 10^5$ | $4 \cdot 10^5$ | $2.7 \cdot 10^5$ | -   |

| Mass  | $6.25-9.5$ | $4-6.25$ | $4.625$ | $4-6.25$ | $2.5-4$ |
| $b_1$ | $1.8$ | $2.5$ | $4$ | $4.9$ | $5.9$ |
| $N_{\text{halo}}$ | $1.7 \cdot 10^5$ | $2.1 \cdot 10^5$ | $1.1 \cdot 10^5$ | $0.4 \cdot 10^5$ | $0.4 \cdot 10^5$ |

The small rotation of the contour levels in the right panel is caused by including data from $z = 2$, which significantly improves the constraints on $g_{NL}$ and only slightly weakens the constraints on $f_{NL}$ (with respect to the current dataset).

### 4.1 Two-parameter model for PNG

We first consider a model ($M_2$) with three free parameters, $f_{NL}$, $g_{NL}$ and $b_1$, and assume Gaussian errors on $b(k)$ to build their likelihood function. We adopt a flat prior within a finite region of parameter space (considerably more extended than the likelihood function) and marginalize the posterior distribution over $b_1$, Fig. 1 shows the marginal posterior probability density for $f_{NL}$ and $g_{NL}$ by marking the 68.3 and 95.4 per cent credibility intervals for the model parameters. The two panels refer to the different sets of mass and redshift bins defined in Table 1 (current data on the left, future data on the right). Different sets of curves in the same panel refer to the different fiducial models used to generate the initial conditions of the simulations. In all cases, the fiducial values for $f_{NL}$ and $g_{NL}$, indicated by the black crosses, lie within the 95.4 per cent credibility region.

The marginal posterior probability distribution for $f_{NL}$ obtained combining the current dataset with model $M_{1f}$ is presented in Fig. 2. The left panel shows the result for the simulation with positive $g_{NL}$ and the right panel for negative $g_{NL}$. Different line styles indicate the individual redshift bins: dotted, long-dashed, dot-dashed for $z = \{0.5, 1, 1.5\}$, while the solid curve shows the combined probability for all redshifts. For the simulation with $g_{NL} = 5 \cdot 10^3$, the resulting 95.4 per cent credibility region (lower horizontal solid line) marginally includes the input value $f_{NL} = 50$, indicated by the vertical dotted line, but the maximum is shifted towards higher values. When $f_{NL}$ and $g_{NL}$ have opposite sign, the maximum a posteriori value is biased low, and the input value is excluded at high significance. In both cases, there is an apparent redshift dependence of $f_{NL}$, and this trend depends on the sign of $g_{NL}$. Thus, if a redshift dependence was ever detected from observations, it may just indicate that the wrong model for PNG is assumed. We note that the results in Xia et al. (2011) actually hint at a redshift dependence.
dependence of $f_{NL}$ although the error bars are quite large. If taken at face value, the ordering of the estimates would suggest that $g_{NL} < 0$.

Additionally, Fig. 2 includes the combined probability for the 5 mass and redshift bins of the future dataset for comparison (short-dashed). The shift away from the input value is qualitatively the same, but larger for the future dataset. This can be understood by comparing the degeneracy between $f_{NL}$ and $g_{NL}$ in Fig. 1.

The marginal posterior probability distribution for $g_{NL}$ under model $M_{1g}$ is shown in Fig. 3. As in the previous figure, the two panels show the results for the simulations with $g_{NL} = \pm 5 \cdot 10^5$. In both cases, the maximum a posteriori estimate is biased high, and the input value lies well outside the 95.4 per cent credibility regions. The estimates from the different redshifts are almost incompatible with each other, and there is no apparent trend with $z$ as seen in model $M_{1f}$. For the case of negative $g_{NL}$, the estimation procedure favours a Gaussian model although both input PNG parameters are substantially different from 0. The combined probability of the future dataset is shown by the short-dashed curve. Here, the shift away from the input value for $g_{NL}$ is smaller, and the constraints are tighter than for the current dataset, in accordance with the rotation of the contours in Fig. 1.

4.3 Model selection

Our results show that the choice of the underlying model for PNG has a significant effect on the estimates of $f_{NL}$ and $g_{NL}$. Only model $M_2$ returned estimates which were in agreement with the fiducial values, while setting a parameter to zero a priori (as often done in the literature) produced biased results. Here we investigate if the data themselves can be used to establish which parameterisation should be preferred.

Given a set of data $D$, the relative evidence in favour of a model with respect to a second one can be quantified in terms of the Bayes factor (e.g. Kass 1993, Trotta 2008)

$$B_{ab} = \frac{P(D| \theta_a)}{P(D| \theta_b)} = \frac{\int L_a(D| \theta_a) \pi_a(\theta_a) \, d\theta_a}{\int L_b(D| \theta_b) \pi_b(\theta_b) \, d\theta_b}. \quad (9)$$

Here $L_a(D| \theta_a)$ gives the probability of getting the data $D$ given the model $M_a$ with parameters $\theta_a$ (i.e. $L_i$ is proportional to the likelihood function for the model parameters), $\pi_i(\theta_i)$ is the prior probability density for the model parameters and $P(D| \theta_i)$ denotes the Bayesian evidence for model $M_i$ (i.e. the probability of getting the data under model $M_i$ after marginalizing over the values of the model parameters).

We find that $M_2$ is strongly favoured over $M_{1f}$ and $M_{1g}$, with a Bayes factor $> 30$, except for one case. Based on the Jeffreys scale (Jeffreys 1961), this provides “very strong” evidence in favour of $M_2$. We thus recommend the use of Bayes factors in future determinations of PNG from observational data based on galaxy 2-point statistics.

5 CONCLUSION

Using two sets of $N$-body simulations starting from non-Gaussian initial conditions of the local type with $\{f_{NL}, g_{NL}\} = \{50, \pm 5 \cdot 10^5\}$, we have investigated the bias of dark-matter halos on large scales. Motivated by the widespread practice of considering only one-parameter models for PNG to fit observational data, we have studied the effect of model assumptions on the determination of model parameters based on 2-point statistics of the galaxy distribution. We have considered two sets of mass and redshift bins: the first one is chosen to emulate the current observational samples, while the second approximates data from future cluster surveys. Our main conclusions can be summarized as follows:

2 Using the current sample, $M_{1f}$ is only disfavoured by a factor of 9 (3) for the simulation with positive (negative) $g_{NL}$.

© 0000 RAS, MNRAS 000, 000–000
Can we measure $f_{\text{NL}}$ from the power spectrum?

Figure 3. Constraints on $g_{\text{NL}}$ for model M$_{1g}$ (where $f_{\text{NL}} \equiv 0$ is assumed a priori). Left panel: simulation with $g_{\text{NL}} = 5 \cdot 10^5$, right panel: simulation with $g_{\text{NL}} = -5 \cdot 10^5$. Line styles are the same as in Fig. 2. The vertical dotted line shows the input value $g_{\text{NL}} = \pm 5 \cdot 10^5$. Note that the long-dashed curve ($z = 1$) seems to be missing in the left panel because the corresponding probability density is too low.

- Fitting the mock data with the input (two-parameter) PNG model gives unbiased results although estimates for $f_{\text{NL}}$ and $g_{\text{NL}}$ turn out to be degenerate. This degeneracy can be at least partially broken using higher-order statistics of galaxy clustering, like the bispectrum.

- If we assume a purely quadratic model ($g_{\text{NL}} = 0$), the maximum a posteriori estimate for $f_{\text{NL}}$ is biased high (low) for the simulations with $g_{\text{NL}} = 5 \cdot 10^5$ ($g_{\text{NL}} = -5 \cdot 10^5$), respectively. The input value of $f_{\text{NL}} = 50$ is almost always excluded at very high confidence. If we consider each redshift bin separately, a spurious systematic shift of the $f_{\text{NL}}$-estimate with $z$ appears, which also depends on the sign of $g_{\text{NL}}$. If seen in observations, this effect could actually indicate the necessity for a more complex model.

- If we assume a purely cubic model ($f_{\text{NL}} = 0$), the maximum a posteriori estimates for $g_{\text{NL}}$ are artificially shifted to larger values, which differ from the input value much more than the broadness of the posterior distribution. When the fiducial PNG parameters have opposite sign, the two contributions to the scale-dependent bias can cancel out, leading to a false null detection.

- Our analysis could be extended by considering even higher-order terms in the expansion of equation (1). However, this phenomenological approach adds degrees of freedom which are not necessarily independent because they may be related to each other through the underlying physics. Alternatively, one could test specific inflationary models and put direct constraints on their properties (e.g. coupling constants) that determine the PNG parameters.

- Given a dataset, statistical model selection techniques are capable to identify the optimal PNG parameterization and thus avoid estimation biases due to incorrect simplifying assumptions. The Bayes factor very strongly favours the two-parameter model over a purely quadratic or purely cubic model for our simulations. It is thus important to apply this model selection to future constraints on PNG from observational data.

6 ACKNOWLEDGEMENTS

NR would like to thank Annalisa Pillepich for help with GADGET-2. The simulations were performed at the Leibniz-Rechenzentrum (LRZ) in Garching, Germany. We acknowledge support through the SFB-Transregio 33 “The Dark Universe” by the Deutsche Forschungsgemeinschaft (DFG).
