We performed high-pressure transport studies on the flat-band Kagome compounds, Pd$_3$P$_2$(S$_{1-x}$Se$_x$)$_8$ ($x = 0, 0.25$), with a diamond anvil cell. For both compounds, the resistivity exhibits an insulating behavior with pressure up to 17 GPa. With pressure above 20 GPa, a metallic behavior is observed at high temperatures in Pd$_3$P$_2$S$_8$, and superconductivity emerges at low temperatures. The onset temperature of superconducting transition $T_c$ rises monotonically from 2 K to 4.8 K and does not saturate with pressure up to 43 GPa. For the Se-doped compound Pd$_3$P$_2$(S$_{0.75}$Se$_{0.25}$)$_8$, the $T_c$ is about 1.5 K higher than that of the undoped one over the whole pressure range, and reaches 6.4 K at 43 GPa. The upper critical field with field applied along the $c$ axis at typical pressures is about 50% of the Pauli limit, suggesting a 3D superconductivity. The Hall coefficient in the metallic phase is low and exhibits a peaked behavior at about 30 K, which suggests either a multi-band electronic structure or an electron correlation effect in the system.

Kagome lattice systems have been proposed to host rich physics, such as quantum spin liquid and unconventional superconductivity in systems with strong electron correlations. Recently, the electronic flat band and Dirac cones were also observed and caused intense research interests in several metallic kagome materials, where the electron correlations appear to be weak. In the Kagome lattice, the flat band arises from phase destruction of electron wave functions in the corner shared triangles, so that one electron band is localized in the hexagons. Theoretically, the high electronic density of states in the flat band is expected to enhance the correlation effect if the flat band is close to the Fermi surface, which may give rise to unusual phenomena such as high $T_c$ superconductivity, fractional quantum Hall effect and ferromagnetism.

Unfortunately, the electron correlations in the flat-band Kagome materials seem to be too weak to offer any novel phase so far. In parallel, signatures of flat bands and the related novel phases have been discovered experimentally in twisted bilayer graphene, silicene and dichalcogenides. An alternative way to look for novel phases is to tune the materials by doping or pressure, so that the electrons can be partly delocalized and bring in the electron correlation effect. In this regard, candidate Kagome materials having flat band close to Fermi surface, such as CoSn and Pd$_3$P$_2$S$_8$, are favored for further study by doping or pressure tuning.

Here we report our high-pressure transport studies on a van-der-Waals Kagome compound Pd$_3$P$_2$S$_8$ and its Se-doped compound Pd$_3$P$_2$(S$_{0.75}$Se$_{0.25}$)$_8$, both of which are highly insulating at the ambient pressure. Pd atoms in Pd$_3$P$_2$S$_8$ constitute the Kagome plane, as shown in Fig. 1. Local density approximation (LDA) calculations on Pd$_3$P$_2$S$_8$ reveal that a flat band, mainly formed by the $d_{z^2}$ orbital of Pd$^{2+}$, is located at about 0.2 eV below the Fermi surface. Se doping enhances the interlayer coupling and reduces the gap of the flat band.

Our high-pressure transport studies show that for both compounds, the conductivity at 300 K is enhanced under pressure. At about 17 GPa, an insulating behavior is still seen. However, their conductivity exhibits a power-law temperature dependence in two decades of temperature below 300 K, which suggests strong electron localization caused by disorder. With further increase of pressure above 20 GPa, a metallic behavior is induced at high temperatures. Superconductivity emerges at low temperatures in the metallic phase. The upper critical field is also found very high with field applied along the $c$ axis. A small Hall coefficient is also observed in the metallic phase and exhibits a strong temperature dependence, which suggests that the system may have an electronic corre-
$\rho \sim 1/T^{0.801}$, to the data at 17 GPa. Insert: An enlarged view of low-temperature resistivity. lution effect.

Pd$_3$P$_2$(Si$_{1-x}$Se$_x$)$_8$ ($x=0, 0.25$) single crystals were grown by the chemical vapor transport method\cite{14, 15}. As shown in Fig. 1(a), Pd$_3$P$_2$S$_8$ has a quasi-2D structure with S1-Pd-S1-P-S2 stacked sequentially along the c axis with an interlayer distance $c = 7.247 \text{ Å}$, and Pd atoms form a perfect kagome structure with the atomic distance $d_{\text{Pd-Pd}} = 3.418 \text{ Å}$\cite{15}. Se doping replaces S atoms randomly and enhances the interlayer coupling\cite{15}, which leads to a larger dispersion and a reduction of gap of the flat band. Note that $x = 0.25$ is the maximal Se doping level currently available\cite{15}.

We performed high-pressure transport measurements with a BeCu diamond anvil cell (DAC). Diamond anvils of 300 μm culets and a rhenium gasket covered with cubic boron nitride (c-BN) powder were used, with no pressure transmitting medium filled in. The highest pressure we achieved is 43 GPa. The pressures were calibrated by the Raman spectrum from the culet of a top diamond anvil and fluorescence from the ruby using a Raman microscope (WITec Alpha 300R). For the transport measurements, the DAC, with sample loaded inside, is cooled in a Quantum Design Physical Property Measurement System (PPMS-14T). The in-plane resistivity and the Hall resistivity of samples were performed by the standard van der Pauw method. Three single crystals, cut into dimensions of $100 \times 100 \times 15 \mu m^3$, were measured. Two of them are undoped, labeled as S1 and S2 respectively, and one is doped, labeled as Se1.

The resistivity of three crystals is first measured with increasing pressures at zero field, and cooled from 300 K down to 2 K. Detailed data are shown as functions of temperatures in Fig. 2(a)-(c). At ambient pressure, the resistance $\rho$ of all three samples is large at room temperature and is barely measurable at low temperatures. This is consistent with the gapped behavior, where all the bands are away from the Fermi surface\cite{15}. With applied pressure, the resistivity $\rho$ decreases for all samples, as shown in Fig. 2(a)-(c). For sample S1, the insulating behavior still holds under pressures of 17 and 21 GPa, as shown by the increase of resistivity upon cooling.

At 17 GPa, the conductivity of sample S1 is found to follow a power-law pressure dependence, that is, $\rho \sim 1/T^\alpha$ with the power-law exponent $\alpha = 0.801 \pm 0.001$, as shown by the fit in Fig. 2(a). The fitting holds in nearly two orders of temperature range below 300 K. By contrast, our data cannot be well fit to a gap function. This power-law pressure dependence of conductivity suggests that insulating behavior is caused by strong electron localization, as a result of disorder in the system\cite{37, 39}. In fact, it is found that $\alpha = 1$ for two-dimensional (2D) systems\cite{40} and $\alpha$ ranges between 1/3 and 1/2 for 3D systems\cite{39, 41}. Our value of $\alpha = 0.8$ indicates that the system crossovers from the 2D to 3D at 17 GPa, which suggests that interlayer coupling is strongly enhanced under pressure. Note that the sample at the ambient pressure shows a high quality as revealed by our XRD data\cite{15}, which leads us to speculate that the disorder effect is either an intrinsic pressure-induced structural disorder of the material, or brought in by pressure inhomogeneity under such high pressures.

A very weak upturn in resistivity is still observed at 21 GPa for sample S1, which suggests that the insulating behavior tends to be suppressed at pressures above 20 GPa. At and above 23 GPa, the resistivity decreases weakly upon cooling, which is a clear signature of a metallic behavior. An enlarged view of the low-temperature resistivity, at pressures above 20 GPa, is further demonstrated in the inset of Fig. 2(a). A high conductivity is seen with resistivity less than 0.5 mΩ cm at room temperature. Since the resistivity does not show a large upturn upon cooling at low temperatures, a metallic, rather than an insulating behavior, is clearly established with pressure above 20 GPa.

Therefore, an insulating to metallic transition is revealed at about 20 GPa in samples S1. Similar transition is also ob-
Fig. 2(c). Such a lower α fit with α_{Se1}, the conductivity at 17 GPa also follows the power-law. Interestingly, the insulating to metallic transition for all three samples in the phase diagram in Fig. 3. Below 20 GPa, an insulating phase is established by the prominent resistivity upturn; whereas above 20 GPa, the absence of resistivity upturn reveals an onset of a metallic phase which turns level off, which signals the disappearance of superconductivity; then the upper critical field \( H_{C2} \) of both crystals is plotted as functions of temperature. Above a specific temperature, resistivity exhibits a drop of normal-state resistivity is 10% shown in (a) and (b). The solid lines in (c) are linear function fits of \( H_{C2}(T) \) for samples S1 and Se1, respectively.

It is also interesting to note that the \( T_c \) for the doped sample is about 1.5 K higher than the undoped one in the whole pressure range. In all compounds, superconductivity is not observed with pressure below 20 GPa, regardless of doping. This will be further discussed later.

Recently, two other studies on Pd_{2}P_{2}S_{8} also report the pressure-induced superconductivity after this work, with \( T_c \) increasing monotonically with pressure. In Ref. 42, the onset pressure for superconductivity is about 10 GPa lower than ours, and \( T_c \) is about 2 K higher at the same pressures. In fact, a pressure-induced amorphous phase is found by the XRD and Raman scattering, which emerges simultaneously with superconductivity. The difference of \( T_c \) may be caused by the pressure transmission medium used in different groups, since the amorphous phase should rely sensitively on the pressure conditions, as revealed by the strong hysteresis of superconductivity with pressure 42.

The out-of-plane upper critical field of superconductivity is also studied by the resistivity measurements with field applied along the crystalline \( c \) axis. The resistivity of samples S1 and Se1 are shown as functions of pressures in Fig. 4(a)-(b) with different fields, each under a fixed pressure. For each fixed field, the resistivity of sample S1 measured at 36 GPa, as shown in Fig. 4(a), first rises from zero with increasing temperature. Above a specific temperature, resistivity exhibits a level off, which signals the disappearance of superconductivity; then the upper critical field \( H_{C2} \) at that temperature is determined as shown in Fig. 4(a). The \( H_{C2} \) of sample Se1 is also determined in the same way with data shown in Fig. 4(b), under a fixed pressure of 43 GPa.

The \( H_{C2} \) of both crystals is plotted as functions of temperatures in Fig. 4(c), which decreases with temperature. At low temperatures, \( H_{C2} \) drops almost linearly with field. Extrapolation to the zero temperature limit gives \( H_{C2}(T=0) \approx 3.68 \) T for sample S1, and \( H_{C2}(0) \approx 7.0 \) T for sample Se1. Consider the amorphous phase should rely sensitively on the pressure conditions, as revealed by the strong hysteresis of superconductivity with pressure 42.
er the onset $T_C$ at zero field is about 4.08 K (6.4 K) for sample S1 (Se1), the zero temperature $H_{C2}$ is then about 50% of the Pauli limit\cite{41,42}, assuming $g = 2$. Such a high out-of-plane $H_{C2}$ suggests that the system is likely a 3D superconductor, which is consistent with the resistivity measurements where a 2D to 3D crossover is already observed at 17 GPa as discussed above. Note that a high out-of-plane critical field is also reported in the iron-based superconductors\cite{47}.

To further understand the carrier properties, the Hall resistivity $\rho_{xy}$ on sample S1 is measured with field applied along the $c$ axis, under a pressure of 36 GPa. As shown in Fig. 5(a), $\rho_{xy}$, plotted as functions of fields measured at different temperatures, shows a linear field dependence with field up to 4 T. By taking the slope of the Hall resistivity, the Hall coefficient $R_H$ is then calculated and plotted as a function of temperatures in Fig. 5(b). Both $\rho_{xy}$ and $R_H$ are calibrated by the high-pressure lattice parameters reported in Ref. 43. $R_H$ stays positive with temperatures from 200 K to 8 K, which suggests that the major carriers are the hole type in the system under pressure. However, $R_H$ changes largely with temperature and is peaked at about 30 K. Such a dramatic temperature dependence suggests that the compounds either have multi electronic bands on the Fermi surface\cite{48,49}, and/or have strong electron correlations\cite{49,50}.

In fact, the values of $R_H$ in the whole temperature range are very small, whose peak value reads $1.89 \times 10^{-4}$ cm$^3$ C$^{-1}$ at 30 K. Taking the value of $R_H$ at 10 K, the carrier concentration is estimated as $3.90 \times 10^{22}$ cm$^{-3}$ at this pressure, assuming a single band. However, this would suggest that each unit cell contains an excessive carrier density of 9.26 holes per unit cell at 10 K. To understand the small and temperature-dependent $R_H$, we propose two alternative scenarios as described below.

The first scenario is based on the nearly compensated electron and hole bands on the Fermi surface. If the system contains both hole and electron types of carriers at high pressures, the value of $R_H$ can be very small as observed. Together with the large temperature-dependent $R_H$ as described above, a pressure-induced multi-band system, with both electron and hole types of carriers on the Fermi surface, is suggested for the high pressure phase. Comparing with the band structure calculations\cite{15}, the $d_{x^2-y^2}$ band of Pd$^{2+}$ is only slightly below the Fermi surface, which may constitute the hole band. By contrast, the $d_{x^2-y^2}$ orbital is located at about 1.5 eV above the Fermi surface, which may become the electron band at high pressures.

The second scenario is based on the correlation effect of the flat band. With more portion of the (nearly) flat band pushed to the Fermi surface under pressure, both the carrier density and the electron correlation effect may be strongly enhanced simultaneously, which result in the temperature-dependent Hall coefficient with a small value. Given the non-monotonic change of the Hall coefficient with temperature, the electron correlation scenario is favored.

To our knowledge, this is a rare superconductor derived from a Kagome compound with a flat band. We now attempt to understand the pressure and Se doping effect in all the samples. As reported, the emergence of superconductivity depends on the pressure-induced structural transition from the crystalline to amorphous phase\cite{42,43}. The emergence of the amorphous phase is consistent with our resistivity data, where large disorder is already observed in the low-pressure phase by the power-law temperature dependence of conductivity. At pressures above 20 GPa, however, the large carrier density may mask the power-law behavior in the conductivity. In principle, further increase of pressure may push the flat band more dispersive, which results in higher carrier concentration on the Fermi surface and enhances $T_C$ consequently. Se doping may also enhance $T_C$ by the increase of the hopping elements with more extended orbitals of Se. On the other hand, the emergence of superconductivity relies only on the external pressure which causes the amorphous phase, so that superconductivity occurs at a similar pressure for both the parent and the doped compounds.

In summary, our high-pressure transport studies on the undoped and the Se-doped Pd$_3$P$_2$S$_8$ reveal that the resistivity changes from an insulating to a metallic behavior at about 20 GPa. The power-law temperature dependence of conductivity at low pressure suggests a high level of disorder induced by pressure, with a 2D to 3D crossover. Superconductivity is observed in the metallic phase for all the compounds. The out-of-plane $H_{C2}$ is high, which again suggests a 3D nature of superconductivity. The superconducting transition temperature $T_C$ rises with pressure at least up to 43 GPa. 25% Se doping further enhances $T_C$ by 1.5 K. Our data suggest that the high-pressure phase likely has both electron and hole bands on the Fermi surface, or strong electron correlations, as revealed by the small value of the Hall coefficient and its large, non-monotonic temperature dependence.
