Abstract. The discretization of certain integral equations, e.g., the first-kind Fredholm equation of Laplace’s equation, leads to symmetric positive-definite linear systems, where the coefficient matrix is dense and often ill-conditioned. We introduce a new preconditioner based on a novel overlapping domain decomposition that can be combined efficiently with existing fast direct solvers. Empirically, we observe that the condition number of the preconditioned system is \(O(1)\), independent of the problem size. Our domain decomposition is designed so that we can construct approximate factorizations of subproblems efficiently. In particular, we apply the recursive skeletonization algorithm to subproblems associated with every subdomain. We present numerical results on problem sizes up to \(16384^2\) in 2D and \(256^3\) in 3D, which were solved in less than 16 hours and three hours, respectively, on an Intel Xeon Platinum 8280M.

Fig. 1: Given two sets of points $\mathcal{B}_1$ and $\mathcal{B}_2$ inside two boxes, respectively. If the two boxes are adjacent (weak admissibility), i.e., $\ell = 0$, then the numerical rank of the off-diagonal block $A(\mathcal{B}_1, \mathcal{B}_2)$ is $O(L)$. On the other hand, if the two boxes are well-separated (strong admissibility), i.e., $\ell = O(L)$, then the numerical rank of the off-diagonal block $A(\mathcal{B}_1, \mathcal{B}_2)$ is $O(1)$.

1.1. Previous work. Since $A$ is a dense matrix, classical direct methods such as Gaussian elimination require $O(N^3)$ operations and $O(N^2)$ storage. Such costs limit the application of these methods to solving only small problems.

Although $A$ is a dense matrix, in many applications it is data sparse in the sense that the singular values of certain off-diagonal blocks in $A$ decay exponentially fast. This is typically the case for matrices related to integral equation formulations of problems with non-oscillatory coefficients and kernels. The numerical low-rank property is exploited in the fast multipole method (FMM) [8,14,17,21,24,41], which requires only $O(N)$ operations and storage for applying $A$ to a vector. Such a fast matrix-vector multiplication can be coupled with iterative methods such as the conjugate gradient method [30] to solve (1.2). However, the number of iterations can be large when the condition number of $A$ is large. Such a situation occurs when (1.1) is a first-kind Fredholm integral equation, i.e., $a(x) = 0$; when $b(x)$ or $c(x)$ exhibits high contrast; or when the problem domain $\Omega$ has a complex geometry.

To accelerate the convergence of an iterative method for solving (1.2), the block Jacobi preconditioner is arguably the simplest preconditioner but may not be particularly effective. It was observed empirically that the single-level additive Schwarz preconditioner with overlapping blocks led to better convergence for some realistic engineering applications [27, 28]. Previous work on two-level additive Schwarz preconditioners mainly focused on analyzing the condition number of the preconditioned linear system. In [33] and [26], the authors introduced two-level additive Schwarz preconditioners to solve first-kind boundary integral equations for the Laplace’s equation on a curve in $\mathbb{R}^2$ and on an open surface in $\mathbb{R}^3$, respectively. In [33], overlapping domain decomposition was used, and it was proved that the condition number of the preconditioned linear system is bounded only if the coarse mesh size is proportional to the size of overlap. In [26], non-overlapping domain decomposition was used, and it was proved that the condition number of the preconditioned linear system still depends on the ratio between the sizes of the coarse mesh and the fine mesh. Recently, the authors of [4] introduced a two-level additive Schwarz preconditioner based on overlapping domain decomposition, which showed great potential in solving indefinite dense linear systems from the discretization of the Lippmann-Schwinger equation. For a more detailed discussion on existing preconditioners for solving discretized integral equations, we refer interested readers to [29] and the references therein.

Fast direct solvers (FDS’s) are a class of methods that construct approximate factorizations with a tunable accuracy. When the accuracy is low, they can be used...
as preconditioners; otherwise with a high accuracy, they behave similarly as a direct method that is suitable for solving multiple right-hand sides. The basic idea of an FDS is to compress certain off-diagonal blocks in $A$ to a prescribed accuracy because they are numerically low rank. This class of methods can be further divided into two groups based on which off-diagonal blocks are compressed or the admissibility criteria; see Figure 1.

The first group employs the so-called weak admissibility and compresses off-diagonal blocks corresponding to two spatially adjacent regions. The resulting numerical ranks typically increase proportionally to the perimeter or the surface area of the regions in 2D or 3D, respectively. Consequently, the construction time of these methods typically scale as $O(N^{3/2})$ and $O(N^2)$ in 2D and 3D, respectively [2,6,7,15,16,19,23,36,38]. Assuming the same rank behavior on the Schur complement, this type of methods can be further accelerated to attain quasilinear complexity [11,20,37]. But existing numerical results seem to indicate that reaching the asymptotic regime requires a really large problem size in 3D.

The second group employs the so-called strong admissibility and compresses off-diagonal blocks corresponding to two sufficiently distant regions [1,12,25,31,32]. The resulting numerical ranks are constant regardless of the sizes of the regions according to standard fast multipole estimates [17,18]. Consequently, these methods can achieve quasilinear complexity assuming the constant-rank estimates also hold for the Schur complement, which appears be true in practice but lacks firm theoretical support. In practice, the constants in the asymptotic scalings tend to be quite large, especially in 3D, because off-diagonal blocks corresponding to adjacent regions are treated exactly without compression.

**1.2. Contributions.** We introduce a new preconditioner based on overlapping domain decomposition to solve (1.2) iteratively with the preconditioned conjugate gradient (PCG) method. The key feature is that the number of iterations required is $O(1)$, independent of the problem size. Our method is based on an empirically observation of the single-level additive-Schwarz preconditioner (Schwarz preconditioner $T^{-1}_{\text{Schwarz}}$ hereafter): the minimum eigenvalue of the preconditioned matrix is lower bounded away from zero. In other words, there exists a positive constant $C > 0$ such
that \( \lambda_{\min}(T_{\text{Schwarz}}^{-1}A) \geq C \). Our preconditioner is associated with a new strategy for constructing an overlapping domain decomposition that has a fixed number of subdomains, and we apply an FDS as a subdomain solver to construct the preconditioner efficiently. In the following, we illustrate these ideas in more details.

Let a partitioning (non-overlapping decomposition) of the problem domain be

\[
\Omega = \bigcup_{i=1}^{M} \mathcal{P}_i, \quad M = \mathcal{O}(N),
\]

where \( \mathcal{P}_i \cap \mathcal{P}_j = \emptyset \) if \( i \neq j \). An overlapping decomposition \( \Omega = \bigcup_{i=1}^{M} \tilde{\mathcal{P}}_i \) is obtained by extending \( \mathcal{P}_i \) to overlap with its neighbors, so that \( \mathcal{P}_i \subset \tilde{\mathcal{P}}_i \) and \( \mathcal{P}_j \cap \tilde{\mathcal{P}}_i \neq \emptyset \) if \( \mathcal{P}_i \) and \( \mathcal{P}_j \) are spatially adjacent. See Figures 2a and 2c for two examples of the domain decomposition corresponding to \( M = 4 \) and 16, respectively. In the Schwarz preconditioner, every \( \tilde{\mathcal{P}}_i \) is a subdomain, and we solve \( M \) corresponding subproblems, which are diagonal sub-blocks in \( A \) (up to a permutation). The Schwarz preconditioner \( T_{\text{Schwarz}}^{-1} \) can be viewed as a generalization of the block Jacobi preconditioner \( T_{\text{Jacobi}}^{-1} \), where a subproblem is associated with \( \mathcal{P}_i \) rather than \( \tilde{\mathcal{P}}_i \). Numerical results show that \( \lambda_{\min}(T_{\text{Schwarz}}^{-1}A) \geq C > 0 \), whereas \( \lambda_{\min}(T_{\text{Jacobi}}^{-1}A) \) decreases toward zero as \( N \to \infty \).

The new overlapping domain decomposition that we introduce is a coloring-based decomposition (CBD). The key feature of the CBD is that the number of subdomains is fixed, and every subdomain \( \Omega_i \) consists of spatially distant \( \tilde{\mathcal{P}}_i \)'s. See Figures 2b and 2d for two examples of a subdomain in the CBD corresponding to \( M = 16 \) and 64, respectively. To compute such a decomposition, we apply graph coloring to the adjacency graph of \( \{\mathcal{P}_i\}_{i=1}^{M} \), so every \( \mathcal{P}_i \) (and \( \tilde{\mathcal{P}}_i \)) is assigned a color \( c_i \). Then, a subdomain \( \Omega_i \) consists of \( \tilde{\mathcal{P}}_k \)'s of the same color, i.e.,

\[
\Omega_i \triangleq \{ \tilde{\mathcal{P}}_k : \text{the color } c_k \text{ assigned to } \tilde{\mathcal{P}}_k \text{ is } i \} = \bigcup_{c_k=i} \tilde{\mathcal{P}}_k.
\]

Given a CBD, we define the corresponding preconditioner (CBD preconditioner hereafter) \( T_{\text{CBD}}^{-1} \) following the same algebraic formulation of the Schwarz preconditioner except that a subproblem \( A_i \) is associated with a subdomain \( \Omega_i \) instead of a single \( \mathcal{P}_i \). As a result, the diagonal blocks in \( A_i \) (with an appropriate permutation) are the subproblems in a related Schwarz preconditioner. In other words, the CBD preconditioner incorporates more information (off-diagonal blocks) from the global problem \( A \). So we expect \( T_{\text{CBD}}^{-1} \) to be a better preconditioner than \( T_{\text{Schwarz}}^{-1} \) and thus \( \lambda_{\min}(T_{\text{CBD}}^{-1}A) \geq \lambda_{\min}(T_{\text{Schwarz}}^{-1}A) \geq C > 0 \). Under mild assumptions, the number of subdomains is upper bounded. For example, we have at most four subdomains in 2D and eight subdomains for a uniform partitioning in 3D. This implies that the maximum eigenvalue of the preconditioned matrix is upper bounded. Therefore, the condition number of \( T_{\text{CBD}}^{-1}A \) is bounded; consequently, (1.2) can be solved in \( \mathcal{O}(1) \) PCG iterations.

To accelerate the construction and reduce the memory footprint of the CBD preconditioner, we apply an FDS to \( A_i \) associated with every subdomain \( \Omega_i \). For demonstration, we employ the recursive skeletonization (RS) factorization [20] based on weak admissibility. RS has a relatively simple formulation, and its theoretical complexity is well understood (without any rank assumptions on the Schur complement). If the RS is applied to the global problem \( A \) directly, the problem domain \( \Omega \) is partitioned at multiple scales, and then the interaction between every pair of adjacent regions is compressed recursively down to the leaf (finest) level. At the leaf level, we
have \( \Omega = \bigcup_{i=1}^{M} \mathcal{P}_i \), where the interaction rank is proportional to the perimeter or the surface area of every \( \mathcal{P}_i \) in 2D or 3D, respectively. This type of rank estimation also holds for coarse partitioning.

Consider a subdomain \( \Omega_i \) in the CBD preconditioner, which consists of distant regions at the leaf level. When we apply RS to \( A_i \) associated with \( \Omega_i \), the separation distance among regions leads to significantly smaller number of skeletons at all scales, compared to the case when these regions are adjacent. In particular, the interaction rank between every pair of regions at the leaf level is provably constant (as in the FMM) because they satisfy the strong admissibility condition. As a result, the construction cost of the CBD preconditioner is much smaller than that of applying the RS to \( A \) directly.

Finally, we clarify that it is not as efficient as the CBD preconditioner if we fix the number of subdomains in the Schwarz preconditioner (problem size per subdomain increases as \( \mathcal{O}(N) \)) and employ the RS as the subdomain solver. The reason is basically the same as above that the interaction rank between a pair of adjacent regions is larger than that between a pair of distant regions. So the cost associated with every subdomain is larger than that in the CBD preconditioner. See more details in Remark 4.8.

1.3. Outline and notations. In Section 2, we introduce a model problem and overlapping domain decompositions that we use throughout this paper. In Section 3, we define the Schwarz preconditioner \( T_{\text{Schwarz}}^{-1} \) and show the crucial observation that \( \lambda_{\text{min}}(T_{\text{Schwarz}}^{-1} A) \geq C > 0 \). In Section 4, we introduce the CBD preconditioner \( T_{\text{CBD}}^{-1} \), show results on the spectrum of \( T_{\text{CBD}}^{-1} A \), and discuss using the RS to construct \( T_{\text{CBD}}^{-1} \) efficiently. In Section 5, we present numerical results to demonstrate the performance of the CBD preconditioner, and Section 6 draws conclusions.

We adopt the MATLAB notation of submatrices, e.g., \( A(I,:) \) and \( A(:,I) \) denote the rows and columns in matrix \( A \) corresponding to an index set \( I \), respectively.

2. Model problem and domain decomposition. In this section, we introduce a model problem and the discretized linear system to be solved. We also present two strategies for constructing an overlapping domain decomposition \( \Omega = \bigcup_{i=1}^{D} \Omega_i \), where \( \Omega \subset \mathbb{R}^d \) is the problem domain (\( d = 2 \) or 3), \( \Omega_i \)'s are overlapping subdomains, and \( D \) is the number of subdomains.

For illustration purpose, we assume \( \Omega = [0,1]^d \), a uniform discretization grid of size \( N = n^d \), and a uniform partitioning of the grid with \( M = m^d \) partitions, where \( n \) and \( m \) are the number of grid points and partitions per dimension, respectively. So every partition has \( N/M = (n/m)^d \) grid points. In this paper, we always assume \( M = \mathcal{O}(N) \) unless stated otherwise, so the number of points per partition is fixed to be \( N/M = \mathcal{O}(1) \).

In Section 2.1, we introduce a model problem and the corresponding discretization. In Section 2.2, we introduce the overlapping domain decomposition for the Schwarz preconditioner, where the number of subdomains equals the number of partitions, i.e., \( D = M \). In Section 2.3, we introduce the CBD strategy, where the number of subdomains \( D = 2^d \). These setups are used throughout this paper for numerical results.

2.1. IE for Laplace’s equation. We focus on a prototypical example of (1.1), the first-kind volume IE of Laplace’s equation in 2D and 3D:

\[
(2.1) \quad \int_{\Omega} K(x-y) u(y) \, dy = f(x), \quad x \in \Omega = [0,1]^d,
\]
where $K(r) \equiv K(x - y)$ is the fundamental solution of the free-space Laplace’s equation, i.e.,

\[
K(r) = \begin{cases} 
-\frac{1}{2\pi} \log(||r||), & d = 2, \\
\frac{1}{4\pi ||r||}, & d = 3.
\end{cases}
\]

Here $u(x)$ is a scalar, and the extension of our approach to cases where $u(x)$ is a vector (e.g., in the Stokes equation) is straightforward.

For simplicity, we discretize (2.1) with a piecewise-constant collocation method over a uniform grid as follows. In 2D, let $h = 1/n$ and $x_j = h(j_1 - 1/2, j_2 - 1/2)$, where $j$ is the index for an integer pair $(j_1, j_2)$ for $1 \leq j_1, j_2 \leq n$. Using the trapezoidal rule and all $x_j$’s as the collocation points, (2.1) is discretized into the following linear system

\[
\sum_j A_{ij} u_j = f_i
\]

where $u_j \approx u(x_j)$ is to be solved, $f_i = f(x_i)$ is given, and

\[
A_{ij} = \begin{cases} 
h^2 K(x_i - x_j), & i \neq j, \\
\int_{-h/2}^{h/2} \int_{-h/2}^{h/2} K(r) \, dx \, dy, & i = j,
\end{cases}
\]

can be evaluated using (2.2) and a proper singular quadrature.

In 3D, let $h = 1/n$ and $x_j = h(j_1 - 1/2, j_2 - 1/2, j_3 - 1/2)$, where $j$ is the index for an integer pair $(j_1, j_2, j_3)$ for $1 \leq j_1, j_2, j_3 \leq n$. The same procedure as above leads to

\[
A_{ij} = \begin{cases} 
h^3 K(x_i - x_j), & i \neq j, \\
\int_{-h/2}^{h/2} \int_{-h/2}^{h/2} \int_{-h/2}^{h/2} K(r) \, dx \, dy \, dz, & i = j.
\end{cases}
\]

Empirically, the condition number of matrix $A$ increases as $O(1/h^2)$, where $h$ is the mesh spacing. That is,

\[
\text{cond}(A) = \begin{cases} 
O(N), & d = 2, \\
O(N^{2/3}), & d = 3.
\end{cases}
\]

(The same behavior as the discretized Laplace operator.)

2.2. Overlapping domain decomposition. Let a uniform partitioning or non-overlapping domain decomposition of the problem domain $\Omega = [0, 1]^d$ be

\[
\Omega = \bigcup_{i=1}^{M} \mathcal{P}_i,
\]

where $M = O(N)$, and $\mathcal{P}_i \cap \mathcal{P}_j = \emptyset$ if $i \neq j$; see Figure 3a for an example. An overlapping domain decomposition $\Omega = \bigcup_{i=1}^{M} \tilde{\mathcal{P}}_i$, follows by extending $\mathcal{P}_i$ to overlap with all of its spatially adjacent partitions $\mathcal{P}_j$, i.e., $\mathcal{P}_i \subset \tilde{\mathcal{P}}_i$ and $\mathcal{P}_j \cap \tilde{\mathcal{P}}_i \neq \emptyset$. In particular, we extend every partition $\mathcal{P}_i$ to include one extra layer of grids in every direction (when possible) to form $\tilde{\mathcal{P}}_i$; see Figure 3b for an example. Except for those extended partitions near the boundary, every $\tilde{\mathcal{P}}_i$ has $(n/m + 2)^d$ nodes given a uniform partitioning of a uniform grid.

This manuscript is for review purposes only.
Our first overlapping domain decomposition is simply taking \( \Omega_i = \tilde{\mathcal{P}}_i \) as a subdomain. Hence, we get

\[
\Omega = \bigcup_{i=1}^{M} \tilde{\mathcal{P}}_i = \bigcup_{i=1}^{D} \Omega_i,
\]

where \( D = M = \mathcal{O}(N) \) is the number of subdomains. (The right-hand side is the union of overlapping subsets of \( \Omega \), which quals the entire set \( \Omega \).) In Section 3, (2.8) and (2.7) are used to construct the Schwarz preconditioner and the block Jacobi preconditioner, respectively. In the block Jacobi preconditioner, \( \mathcal{P}_i \) is treated as a subdomain.

### 2.3. Coloring-based decomposition.

Given the partitioning in (2.7), we apply graph coloring to the adjacency graph of \( \{\mathcal{P}_i\}_{i=1}^{M} \), where an edge between \( \mathcal{P}_i \) and \( \mathcal{P}_j \) exists if the two partitions are spatially adjacent. As a result, every partition \( \mathcal{P}_i \) (and its extension \( \tilde{\mathcal{P}}_i \)) is assigned a color \( c_i \) in \( \{1, 2, \ldots, N_c\} \), where \( N_c \) is the number of colors; see Figure 3c for an example. With the overlapping domain decomposition in (2.8), we form a subdomain \( \Omega_i \) as

\[
\Omega_i = \{ \tilde{\mathcal{P}}_k : \text{the color } c_k \text{ assigned to } \tilde{\mathcal{P}}_k \text{ is } i \} = \bigcup_{c_k=i} \tilde{\mathcal{P}}_k, \quad i = 1, 2, \ldots, N_c;
\]

see Figure 3d for an example. It is easy to see

\[
\Omega = \bigcup_{i=1}^{M} \tilde{\mathcal{P}}_i = \bigcup_{i=1}^{N_c} \left( \bigcup_{c_k=i} \tilde{\mathcal{P}}_k \right) = \bigcup_{i=1}^{D} \Omega_i,
\]

where \( D = N_c \) is the number of subdomains. We call (2.10) a coloring-based decomposition (CBD), which is used in Section 4 to construct the CBD preconditioner. If the number of partitions \( M = 2^d \) in (2.7), then (2.10) reduces to (2.8) because every subdomain (color) has only one partition.

According to the four color theorem [3], we know \( N_c = 4 \) in 2D. For a general graph in 3D, \( N_c \) can be arbitrarily large but is usually small for practical problems that have some regularity. For example, \( N_c = 8 \) for a uniform partitioning of a uniform grid. To summarize, we state the following:
Table 1: Given a domain decomposition \( \Omega = \bigcup_{i=1}^{D} \Omega_i \), the definition of a subdomain \( \Omega_i \) leads to different preconditioners including the block Jacobi preconditioner (Section 3), the Schwarz preconditioner (Section 3), and the CBD preconditioner (Section 4).

|    | Jacobi | Schwarz | CBD |
|----|--------|---------|-----|
| \( \Omega_i \) | \( P_i \) | \( \tilde{P}_i \) | \( \bigcup_{k=\ell} \tilde{P}_k \) |

**Theorem 2.1.** For a uniform partitioning of a uniform grid over \( \Omega = [0,1]^d \), the number of subdomains (colors) is \( 2^d \) in the CBD.

As a summary of Sections 2.2 and 2.3, Table 1 shows the three preconditioners to be introduced associated with (2.7), (2.8), and (2.10).

**3. Schwarz preconditioner.** Given a domain decomposition \( \Omega = \bigcup_{i=1}^{D} \Omega_i \) (not necessarily an overlapping domain decomposition), we construct a preconditioner as follows. Let \( I_i \) denote the indices of the discretization points in \( \Omega_i \). First, we define the restriction operator for every subdomain \( \Omega_i \):

\[
R_i = I_N(I_i,:),
\]

a subset of rows in the identity matrix \( I_N \in \mathbb{R}^{N \times N} \) corresponding to indices \( I_i \). Then, we define the subproblem associated with \( \Omega_i \):

\[
A_i = R_i A R_i^T.
\]

Finally, we define the preconditioner:

\[
T^{-1} = \sum_{i=1}^{D} R_i^T A_i^{-1} R_i.
\]

With the overlapping domain decompositions (2.8) and (2.10), we obtain the Schwarz preconditioner (technically, single-level additive Schwarz preconditioner) and the CBD preconditioner (Section 4). With the non-overlapping domain decomposition (2.7), we obtain the block Jacobi preconditioner.

In the following, we focus on the Schwarz preconditioner \( T_{\text{Schwarz}}^{-1} \), derive a theorem on \( \lambda_{\text{max}}(T_{\text{Schwarz}}^{-1} A) \), and show empirical results on \( \lambda_{\text{min}}(T_{\text{Schwarz}}^{-1} A) \). We also compare the Schwarz preconditioner to the block Jacobi preconditioner.

**3.1. Maximum and minimum eigenvalues.** Consider the preconditioned matrix

\[
T^{-1} A = \sum_{i=1}^{D} R_i^T A_i^{-1} R_i A.
\]

We define

\[
P_i = R_i^T A_i^{-1} R_i A,
\]

and we can verify that \( P_i \) is an orthogonal projection with respect to the inner product defined by the SPD matrix \( A \):

\[
P_i^2 = P_i, \quad A P_i = P_i^T A.
\]
Table 2: Maximum and minimum eigenvalues of the preconditioned matrix (3.3). The block Jacobi and the Schwarz preconditioners are defined in Table 1. The number of subdomains $D = O(N)$.

| $N$ | $D$ | Jacobi $\lambda_{\max}$ $\lambda_{\min}$ | Schwarz $\lambda_{\max}$ $\lambda_{\min}$ |
|-----|-----|---------------------------------|---------------------------------|
| $8^2$ | $2^2$ | 2.8479 0.1695 | 4.0000 0.8209 |
| $16^2$ | $4^2$ | 6.6883 0.0804 | 8.8046 0.9112 |
| $32^2$ | $8^2$ | 19.3756 0.0533 | 23.5948 0.9350 |
| $64^2$ | $16^2$ | 61.6629 0.0409 | 71.5192 0.9360 |
| $128^2$ | $32^2$ | 205.7705 0.0336 | 231.7813 0.9331 |

(a) Discretized integral operator in 2D; see (2.4).

| $N$ | $D$ | Jacobi $\lambda_{\max}$ $\lambda_{\min}$ | Schwarz $\lambda_{\max}$ $\lambda_{\min}$ |
|-----|-----|---------------------------------|---------------------------------|
| $4^3$ | $2^3$ | 4.0618 0.2602 | 8.0000 0.9750 |
| $8^3$ | $4^3$ | 15.4234 0.2056 | 33.1198 0.9942 |
| $16^3$ | $8^3$ | 60.9327 0.1916 | 134.7002 0.9967 |
| $32^3$ | $16^3$ | 242.9799 0.1878 | 547.3752 0.9972 |

(b) Discretized integral operator in 3D; see (2.5).

As a result, we have $\lambda_{\max}(P_i) = 1$, which immediately leads to the following:

**Theorem 3.1.** Let $A$ be an SPD matrix and the preconditioner $T^{-1}$ defined in (3.2). Then,

$$\lambda_{\max}(T^{-1}A) \leq D,$$

where $D$ is the number of subdomains.

**Proof.** $\lambda_{\max}(T^{-1}A) \leq \sum_{i=1}^{D} \lambda_{\max}(P_i) = D$. □

Note the theorem applies to both the block Jacobi and the Schwarz preconditioners because it only requires a decomposition of the problem domain (not necessarily an overlapping decomposition); see numerical results in Table 2. The table also shows that as the problem size $N$ increases, $\lambda_{\min}(T^{-1}_{\text{Schwarz}}A)$ appears to converge to a positive constant close to one, whereas $\lambda_{\min}(T^{-1}_{\text{Jacobi}}A)$ is much smaller and keeps decreasing. We state the following (and provide more concrete evidence in Section 3.2):

**Conjecture 3.2.** Let $A$ be the discretized integral operator in (2.4) or (2.5). Given the overlapping domain decomposition (2.8), the Schwarz preconditioner $T^{-1}_{\text{Schwarz}}$ is defined in (3.2). Then,

$$\lambda_{\min}(T^{-1}_{\text{Schwarz}}A) \geq C > 0,$$

where $C$ is a positive constant.

**Remark 3.3.** If $A$ is a sparse SPD matrix arising from a local discretization (e.g., by finite elements or finite differences) of a second-order self-adjoint, coercive elliptic
problem, then the upper bound in Theorem 3.1 can be reduced to a constant, independent of the number of subdomains $D$ \cite{5,13}. The reason is that $P_i + P_j$ is still an orthogonal projection when $\Omega_i \cap \Omega_j = \emptyset$ (because $R_i A R_j^\top = 0$ when $A$ is sparse).

Remark 3.4. In the context of solving PDEs, the (single-level additive) Schwarz preconditioner results in a bounded maximum eigenvalue of the preconditioned matrix, whereas the minimum eigenvalue goes to zero as $M = \mathcal{O}(N) \rightarrow \infty$.

3.2. Analysis for $D = 2^d$. In this section, we assume the number of subdomains $D = 2^d$ and study the maximum and minimum eigen-pairs of $T^{-1}_{\text{Schwarz}} A$. The analysis of the maximum eigen-pair prepares for the corresponding analysis for $T^{-1}_{\text{CBD}} A$ in Section 4.1. The observations for the minimum eigen-pair provide insights and evidence for Conjecture 3.2. We also compare the Schwarz preconditioner to the block Jacobi preconditioner, for which Conjecture 3.2 does not hold.

Recall $P_i$ defined in (3.4) is a projection associated with subdomain $\Omega_i$, so we have

**Lemma 3.5.** Let $x \in \mathbb{R}^N$ be nonzero only in $\Omega_i$, i.e., $x = R_i^\top R_i x$. Then,

$$P_i x = x.$$

**Proof.** With the definitions of $A_i$ and $P_i$ in (3.1) and (3.4), respectively, we have

$$P_i x = (R_i^\top A_i^{-1} R_i A) (R_i^\top R_i x) = R_i^\top A_i^{-1} (R_i A R_i^\top) R_i x = R_i^\top R_i x = x.$$

This lemma is useful for analyzing eigenvectors of the preconditioned matrix. The following theorem addresses the maximum eigenvalue and the associated eigenvector of $T^{-1}_{\text{Schwarz}} A$.

**Theorem 3.6.** Suppose the problem domain $\Omega = [0,1]^d$ is partitioned uniformly into $D = 2^d$ overlapping subdomains. Given the overlapping domain decomposition (2.8), we have

$$\lambda_{\text{max}}(T^{-1}_{\text{Schwarz}} A) = 2^d,$$

and the corresponding eigen-space is of dimension $2^d$ and consists of vectors that are nonzero only in the overlapped region shared by all $2^d$ subdomains.

**Proof.** According to Theorem 3.1, we know that $\lambda_{\text{max}}(T^{-1}_{\text{Schwarz}} A) \leq 2^d$. Recall that when $D = 2^d$, we have $\cap_{i=1}^{2^d} \Omega_i \neq \emptyset$, and the shared region contains $2^d$ grid
points; see Figure 4a for an example. Suppose $x$ is nonzero only in the shared region. According to Lemma 3.5, we know that $P_i x = x$ for all $i$. Therefore,

$$T_{\text{Schwarz}}^{-1} A x = \sum_{i=1}^{2^d} P_i x = 2^d x.$$ 

The theorem does not apply to $T_{\text{Jacobi}}^{-1} A$ directly but provides insight on the maximum eigen-pair when the problem size $N \to \infty$. In the limit, all subdomains associated with the block Jacobi preconditioner share the center of the problem domain $\Omega = [0, 1]^d$; see Figure 4b for an example. So we know that

$$\lim_{N \to \infty} \lambda_{\text{max}}(T_{\text{Jacobi}}^{-1} A) = 2d;$$

see numerical results in Table 3. The corresponding eigenvector converges to the indicator function of the center point $x_c$, i.e.,

$$1_{x_c}(x) = \begin{cases} 1 & x = x_c, \\ 0 & \text{else}; \end{cases}$$

see numerical results plotted in Figures 5a and 5c.

Next, we consider the minimum eigen-pair of $T_{\text{Jacobi}}^{-1} A$. We start with an example in one dimension (1D). Suppose the problem domain $\Omega = [0, 1]$ is cut into two halves of equal length ($D = 2$), i.e., $\Omega_1 = [0, 1/2], \Omega_2 = [1/2, 1]$. Suppose a uniform discretization grid has $N$ nodes, where $N$ is an even integer and the discretization points are indexed from left to right. Let the indices of discretization points in $\Omega_1$ and $\Omega_2$ be $I_1 = \{1, 2, \ldots, N/2\}$ and $I_1 = \{N/2 + 1, N/2 + 2, \ldots, N\}$, respectively. Recall the block Jacobi preconditioner $T_{\text{Jacobi}}^{-1}$ defined in (3.2). Consider the eigenvalue problem

$$T_{\text{Jacobi}}^{-1} A x = \lambda x,$$

where $\lambda$ is an eigenvalue. Write $x = x_1 + x_2$, where $x_i = R_i x$ for $i = 1, 2$. We state the following theorem and give the proof in Appendix A.

**Theorem 3.7.** Let $x = x_1 + x_2$ be an eigenvector associated with an eigenvalue $\lambda$ of the preconditioned matrix $T_{\text{Jacobi}}^{-1} A$ in 1D. Then, $x' = x_1 - x_2$ is also an eigenvector, and the corresponding eigenvalue is $2 - \lambda$. In other words,

$$T_{\text{Jacobi}}^{-1} A x = \lambda x \iff T_{\text{Jacobi}}^{-1} A x' = (2 - \lambda) x'.$$

According to the above theorem, (3.5) implies

$$\lim_{N \to \infty} \lambda_{\text{min}}(T_{\text{Jacobi}}^{-1} A) = 0$$

for our example in 1D; see numerical results of eigenvectors in Figures 5a and 5b. One interpretation of the eigenvectors of $T_{\text{Jacobi}}^{-1} A$ from electrostatics is the following. The limit ($N \to \infty$) of the eigenvector associated with $\lambda_{\text{max}}$, namely, (3.6), can be interpreted as putting a point charge at the domain center. The eigenvector associated with $\lambda_{\text{min}}$ corresponds to putting dipoles near the boundaries of adjacent subdomains. For the example in 1D, the boundary is just one point $x_c = 1/2$; see Figure 5b. For the unit square domain in 2D, the boundaries are two lines $1/2 \times [0, 1]$ and $[0, 1] \times 1/2$; see Figure 5d. As a result, the electric potential induced by all charges cancels out.
approximately. Based on this intuition, we conjecture that (3.8) also holds when $d = 2$ and $3$; see numerical results in Table 3.

Finally, we consider the minimum eigen-pair of $T_{\text{Schwarz}}^{-1} A$. Let us revisit the previous example in 1D, where the problem domain $\Omega = [0, 1]$ is discretized with a uniform grid of size $N$ (an even integer) and the grid points are indexed from left to right. To construct the Schwarz preconditioner, we use the overlapping domain decomposition where $\Omega_1$ and $\Omega_2$ contain the first and the last $N/2 + 1$ grid points, respectively. Figure 6a shows the eigenvector corresponding to $\lambda_{\text{min}}$. In the figure, there is a “dipole” at the overlapped region, and the eigenvector decays more slowly away from the boundary than that in Figure 5b. This observation extends to higher dimensions, and the differences between the two eigenvectors for $\lambda_{\text{min}}$ are more pronounced in 2D; compare Figure 6b to Figure 5d. Both eigenvectors contain “dipoles” near the boundaries of the four subdomains in 2D. For the eigenvector associated with the Schwarz preconditioner, the “dipoles” mainly concentrate around $(1/2, 0), (1/2, 1), (0, 1/2)$ and $(1, 1/2)$ on the boundary of the square domain. For the eigenvector associated with the block Jacobi preconditioner, however, the “dipoles” mainly exist in the interior of the domain. This empirical observation extends to cases when $D > 2^d$. The difference between the minimum eigenvalues of the preconditioned matrix is shown in Table 3 for problems in 2D and in 3D.

4. Coloring-based decomposition (CBD) and preconditioner. In this section, we introduce the CBD preconditioner based on the decomposition (2.10). Recall
Fig. 6: Eigenvectors of $T_{\text{Schwarz}}^{-1}A$ in 1D ($N = 32, D = 2$) and 2D ($N = 256^2, D = 2^2$). In (a), two dots (in black) lie in the overlapped region of two subdomains, and two curves (in blue and red, respectively) lie in the interior of two subdomains, respectively. The discretized integral operator is given in (2.4).

Fig. 7: (a) a square domain is partitioned uniformly into 16 partitions; (b) shared region (in black) of the four subdomains in the CBD preconditioner. Every subdomain has four separated regions indicated by the index.

that a subdomain consists of spatially distant regions as shown in Figure 3d and the algebraic formulation of the CBD preconditioner is given in (3.2). In Section 4.1, we show that the maximum and minimum eigenvalues of the preconditioned matrix $T_{\text{CBD}}^{-1}A$ are bounded from above and from below, respectively. In Section 4.2, we apply the recursive skeletonization (RS) factorization [20] to construct approximate factorizations of subproblems in the CBD preconditioner, which are used to apply the preconditioner efficiently. In Section 4.3, we compare the CBD preconditioner to the original RS method, and in Section 4.4, we provide some analysis of the CBD preconditioner.

4.1. Spectral equivalence. The number of subdomains used in the CBD preconditioner is typically a constant independent of the problem size. This implies that the maximum eigenvalue of the preconditioned matrix is upper bounded according to Theorem 3.1. In addition, numerical results reveal strong evidence that the minimum eigenvalue is lower bounded away from zero, which can also be justified by...
Table 3: Maximum and minimum eigenvalues of the preconditioned matrix (3.3). The block Jacobi, the Schwarz and the CBD preconditioners are defined in Table 1. The number of subdomains $D = 2^d$ is fixed.

(b) Discretized integral operator in 3D; see (2.5).

Conjecture 3.2. We illustrate these statements with more details in the following.

Consider the maximum eigenvalue of the preconditioned matrix $T_{CBD}^{-1}A$. As previously mentioned in section 2, we assume the problem domain $\Omega = [0, 1]^d$ is discretized with a uniform grid and is partitioned uniformly into $M = m^d$ partitions ($m$ partitions along every dimension); see Figure 7a. In this case, we have $D = 2^d$ subdomains in the CBD preconditioner. There are $(m-1)^d$ overlapped regions shared by all subdomains; see Figure 7b for an example. When $M = D = 2^d$, the CBD preconditioner is reduced to the Schwarz preconditioner. We generalize the analysis in Section 3.2 and Theorem 3.6 to the following:

**Theorem 4.1.** Suppose the problem domain $\Omega = [0, 1]^d$ is partitioned uniformly. Given the overlapping decomposition in (2.10), where $M = m^d \geq D$, we have

$$\lambda_{\text{max}}(T_{CBD}^{-1}A) = 2^d,$$

and the corresponding eigen-space is of dimension $(2(m-1))^d$ and consists of vectors that are nonzero only in the overlapped region shared by all $2^d$ subdomains.

**Proof.** The proof is almost identical to that of Theorem 3.6, except there are $(m-1)^d$ overlapped regions shared by all subdomains. (Recall that every shared region has $2^d$ discretization points; see Figure 4a.)

Next, we consider the minimum eigenvalue of the preconditioned matrix in (3.3). Assume we are given a partitioning of the problem domain as in (2.7), where the number of partitions $M = O(N)$. We can construct the Schwarz and the CBD preconditioners based on (2.8) and (2.10), respectively. In this case, a subdomain...
in the CBD preconditioner is a union of non-adjacent subdomains in the Schwarz preconditioner. This implies that every subproblem in the Schwarz preconditioner is a diagonal block in a subproblem in the CBD preconditioner. As a concrete example, we have $\Omega_1^{CBD} = \Omega_1^{Schwarz} \cup \Omega_3^{Schwarz} \cup \Omega_9^{Schwarz} \cup \Omega_{11}^{Schwarz}$ in Figure 7. Correspondingly, we know the discretization points satisfy the same relationship, i.e., $I_1^{CBD} = I_1^{Schwarz} \cup I_3^{Schwarz} \cup I_9^{Schwarz} \cup I_{11}^{Schwarz}$. According to the definition (3.1), we have

$$A_1^{CBD} = \begin{bmatrix}
A_1^{Schwarz} & \times & \times & \times \\
\times & A_3^{Schwarz} & \times & \times \\
\times & \times & A_9^{Schwarz} & \times \\
\times & \times & \times & A_{11}^{Schwarz}
\end{bmatrix},$$

where $\times$ stands for the "interaction" between two Schwarz subdomains, entries in the original matrix $A$ but not in any $A_i^{Schwarz}$. In general, the CBD preconditioner uses (much) more entries in the original problem $A$ than the related Schwarz preconditioner. A subproblem $A_i^{CBD}$ contains $O(N/2^d)$ entries in $A$, whereas a subproblem $A_i^{Schwarz}$ contains only $O(1)$ entries. Therefore, we expect the CBD preconditioner to be a better preconditioner. Compare $\lambda_{\min}(T_{CBD}^{-1}A)$ in Table 3 to $\lambda_{\min}(T_{Schwarz}^{-1}A)$ in Table 2. We state the following:

**Conjecture 4.2.** Let $A$ be the discretized integral operator in (2.4) or (2.5). Given the overlapping domain decomposition (2.10), the CBD preconditioner $T_{CBD}^{-1}$ is defined in (3.2). Then, $\lambda_{\min}(T_{CBD}^{-1}A) \geq C > 0$, where $C$ is a positive constant.

### 4.2. Recursive skeletonization (RS) as subdomain solver.

To construct the CBD preconditioner, we apply the RS algorithm to compute an approximate factorization of every subproblem $A_i$ in the CBD preconditioner. The resulting factorizations consist of block triangular factors, which can be inverted easily for applying the preconditioner. Suppose the subproblem $A_i$ is associated with the subdomain

$$\Omega_i = \tilde{M} \bigcup_{k=1}^{\tilde{M}} \tilde{P}_k,$$

where $\tilde{M} = M/D = M/2^d$, and $\tilde{P}_k$'s are spatially distant regions of the same color; see an example in Figure 7b. To simplify notations, we drop the subscript $i$ in $A_i$ for the rest of this section, and we refer interested readers to [20] for more details.

Without loss of generality, write

$$A = \begin{pmatrix}
A_{pp} & A_{pq} \\
A_{qp} & A_{qq}
\end{pmatrix},$$

where rows/columns indices $p$ and $q$ correspond to $\tilde{P}_1$ and the union of remaining regions in (4.1), respectively. Assume $A_{qp}$ is numerically low-rank, we compute the following interpolative decomposition (ID) [10] :

$$A_{qp} = \begin{pmatrix}
A_{qr} & A_{qs}
\end{pmatrix} \approx A_{qs} \begin{pmatrix}
T_p & I
\end{pmatrix},$$

where the index set $p$ is split into a redundant subset $r$ and a skeleton subset $s$ (up to a permutation) and

$$\|A_{qr} - A_{qs}T\| \leq \varepsilon \|A_{qr}\|$$

This manuscript is for review purposes only.
for a prescribed (relative) accuracy $\varepsilon$. We call the indices in $s$ skeletons, which tend to be discretization points close to the boundary of $\tilde{P}_1$. See a pictorial illustration in Figure 8. Define the numerical rank $k = |s|$. Since $\tilde{P}_1$ is well-separated from the remaining regions in (4.1), we know

$$k = O(1),$$

according to standard fast multipole estimates [17, 18]. Computing the ID requires $O(k |p| |q|)$ operations in general but can be accelerated to $O(k |p|^2)$ operations using the so-called proxy trick [22, 41].

With (4.3), we have the approximation

$$A \approx \begin{pmatrix} A_{rr} & A_{rs} & T_p^\top A_{sq} \\ A_{sr} & A_{ss} & A_{sq} \\ A_{qs}T_p & A_{qs} & A_{qq} \end{pmatrix},$$

so we can eliminate the original $A_{rq}$ and $A_{qr}$ blocks without affecting the $A_{qq}$ block:

$$L_p^\top A L_p \approx \begin{pmatrix} B_{rr} & B_{rs} \\ B_{sr} & A_{ss} & A_{sq} \\ A_{qs} & A_{qq} \end{pmatrix}, \quad L_p = \begin{pmatrix} I \\ -T_p & I \end{pmatrix}$$

where

$$B_{rr} = A_{rr} - A_{rs}T_p - T_p^\top A_{sr} + T_p^\top A_{ss}T_p,$$

$$B_{sr} = B_{rs} - A_{ss}T_p.$$

Let $B_{rr} = G_r^\top G_r$ be its Cholesky factorization, and we have the following approximate partial factorization

$$U_r^\top L_p^\top A L_p U_r \approx \begin{pmatrix} I & B_{ss} & A_{sq} \\ A_{qs} & A_{qq} \end{pmatrix}, \quad U_r = \begin{pmatrix} G_r^{-1} \\ -B_{rr}^{-1}B_{rs} \\ I \end{pmatrix}$$

where

$$B_{ss} = A_{ss} - B_{sr}B_{rr}^{-1}B_{rs}.$$

Notice that the $A_{aq}, A_{sq}$, and $A_{qs}$ blocks have not been modified. Define $R_1 = L_p U_r$ corresponding to the first region $\tilde{P}_1$ in (4.1), and we call $R_1$ an “compress-then-eliminate” operator.

We continue the above “compress-then-eliminate” step for the remaining block rows/columns corresponding to each of the remaining regions in (4.1). The resulting Schur complement is a block matrix, where off-diagonal blocks remain sub-matrices in $A$. To be precise, suppose the indices of every block row/column are split into a redundant subset $r_i$ and a skeleton subset $s_i$ for $i = 1, 2, \ldots, M$, then there exists a permutation matrix $Q$ such that

$$Q^\top (R_M^\top \cdots R_2^\top R_1^\top A R_2 \cdots R_M)Q \approx \begin{pmatrix} I & B_{s_1s_1} & A_{s_1s_2} & \cdots & A_{s_1s_M} \\ A_{s_2s_1} & B_{s_2s_2} & \cdots & A_{s_2s_M} \\ \vdots & \vdots & \ddots & \vdots \\ A_{s_Ms_1} & A_{s_Ms_2} & \cdots & B_{s_Ms_M} \end{pmatrix},$$

This manuscript is for review purposes only.
where the first diagonal block has size $\sum r_i$, and every $B_{s_i,s_i}$ is computed analogously to (4.8). Figure 8 shows a pictorial illustration of the row/column indices in the original subproblem $A_i$ and the Schur complement in (4.9).

To continue factorizing the Schur complement (approximately), we need a coarse partitioning of the domain $\Omega_i$. It can be obtained by merging spatially close regions in (4.1). With a coarse overlapping domain, we repeat the above process recursively until only one coarse partition remains. As the last step, we factorize the remaining Schur complement with Cholesky factorization directly. In practice, we compute a hierarchical partitioning of the problem domain $\Omega$, where the decomposition (4.1) is at the first level and the last Schur complement factorized with Cholesky factorization is at the last level. For convenience, we make the following definition:

**Definition 4.3.** The degrees of freedom (DOFs) at every level in a hierarchical partitioning of the problem domain $\Omega$ are the discretization points that have not been processed in the RS algorithm. In particular, we have

- **DOFs at the first level:** discretization points corresponding to $A$ in (4.2);
- **DOFs at the second level:** discretization points corresponding to the Schur complement in (4.9);
- **DOFs at the last level:** discretization points corresponding to the last Schur complement factorized with Cholesky factorization.

Assume in (4.3) the numerical rank $|s_i| \equiv k$ is a constant for all $i$. The number of DOFs at the second level is

\[
\tilde{M} \sum_{i=1}^{\tilde{M}} s_i = k\tilde{M},
\]

which immediately leads to the following:

**Theorem 4.4.** In the CBD preconditioner, the number of DOFs at the second level is $\mathcal{O}(M)$, independent of the original problem size $N$.

Recall that $M = D\tilde{M} = 2^d\tilde{M}$ is the number of partitions of the entire domain $\Omega$. Here, we do not require $M = \mathcal{O}(N)$ as in Section 3. In fact, we show how to choose $\tilde{M}$ to achieve optimal asymptotic scaling in Section 4.4.

**4.3. Comparison to the original RS factorization.** The original RS factorization was applied to matrix $A$ in (1.2) directly, as other FDS’s are typically used.
To that end, the algorithm described in Section 4.2 remains the same except that we replace (4.1) with a partitioning (non-overlapping decomposition) of the entire problem domain as follows

\[(4.11) \quad \Omega = \bigcup_{i=1}^{M} P_i, \quad P_i \cap P_j = \emptyset, \text{ if } i \neq j.\]

In particular, we view matrix \(A\) as a block matrix as in (4.2), where \(p\) and \(q\) correspond to \(P_1\) and \(\bigcup_{i=2}^{M} P_i\), respectively. Then, we compute the ID of \(A_{qp}\) as in (4.3). Since \(P_1\) is spatially adjacent to \(\bigcup_{i=2}^{M} P_i\), we know the following according to Green’s theorem:

\[(4.12) \quad k = \mathcal{O} \left( \left( \frac{N}{M} \right)^{(d-1)/d} \right).\]

With a uniform partitioning, \(P_1\) contains \(N/M\) discretization points, and the numerical rank \(k\) scales as the perimeter or the surface area of \(P_1\) in 2D or 3D, respectively. Compare (4.12) to the numerical rank in (4.5) corresponding to applying the RS to a subproblem \(A_i\) in the CBD preconditioner.

After \(A_{qp}\) is compressed, we follow (4.6) and (4.7), and we repeat the “compress-then-eliminate” step for each of the remaining block rows/columns and obtain the Schur complement as in (4.9). Assuming the numerical rank \(k\) is a constant for all blocks, the resulting Schur complement has size \(kM\). To factorize the Schur complement, we construct a coarse partitioning of \(\Omega\) by merging adjacent partitions in (4.11) and recurse until a single partition is left. Finally, we apply Cholesky factorization to the last Schur complement directly. Figure 9 shows a pictorial illustration of the entire algorithm.

Let \(S\) be the number of DOFs at the last level, and we have the following [20]:

\[(4.13) \quad S = \mathcal{O} \left( \left( \frac{N}{M} \right)^{(d-1)/d} \right).\]

Since work required to factorize the last Schur complement typically dominates that of the RS algorithm, we have the following [20]:

**Theorem 4.5.** The construction cost of applying the RS algorithm to \(A\) in (1.2) is

\[t_f = \mathcal{O} \left( N^{3(d-1)/d} \right) \]

for \(d = 2, 3\), and storing/applying the approximate factorization requires

\[m_f = t_a = \begin{cases} \mathcal{O} \left( N \log N \right), & d = 2, \\ \mathcal{O} \left( N^{4/3} \right), & d = 3. \end{cases}\]
Table 4: Comparison between the original RS factorization [20] (applied to $A$ directly) and the CBD preconditioner (employing RS for every subproblem $A_i$). Results of RS are from (4.12), (4.13), and Theorem 4.5. Results of CBD are from (4.5), Theorems 4.6 and 4.7. The problem dimension $d = 2$ or $3$.

|                       | RS                        | CBD                        |
|-----------------------|---------------------------|----------------------------|
| Off-diagonal rank at first level | $\mathcal{O}\left(\left(\frac{N}{M}\right)^{\frac{d^2}{d^2}}\right)$ | $\mathcal{O}(1)$          |
| # DOFs at last level   | $\mathcal{O}\left(N^{\frac{d^2}{d^2}}\right)$ | $\mathcal{O}\left(M^{\frac{d^2}{d^2}}\right)$ |
| Construction cost      | $CN^3\left(\frac{d^2}{d^2}\right)$ | $\tilde{C}^2CN^{\frac{3(d^2+1)}{d^2}}$ |

Next, we derive results analogous to (4.13) and Theorem 4.5 for the CBD preconditioner. According to Theorem 4.4, the number of DOFs at the second level is $\mathcal{O}(M)$ in the CBD preconditioner. The DOFs corresponds to the Schur complement in (4.9), to which we apply the RS algorithm recursively. If we apply (4.13) to the Schur complement of size $\mathcal{O}(M)$, it is easy to see the following:

**Theorem 4.6.** In the CBD preconditioner, the number of DOFs at the last level is (upper bounded by)

$$S = \mathcal{O}\left(M^{(d^2d)/d}\right).$$

To construct the CBD preconditioner, we apply the RS algorithm to every subproblem $A_i$ for $i = 1, 2, \ldots, 2^d$. In general, suppose we have an FDS with $CN^\alpha$ construction cost, where $C$ is a constant. Then, we immediately have

**Theorem 4.7.** The construction cost of the CBD preconditioner is

$$2^d \cdot \tilde{C} \left(\frac{N}{2^d}\right)^\alpha = \frac{\tilde{C}}{C} \cdot 2^{(\alpha-1)d}CN^\alpha < CN^\alpha,$$

where $d = 2$ or $3$, $\tilde{C} < C$, and $\alpha > 1$. In particular, $\alpha = 3(d-1)/d$ for the RS factorization.

Here, the fact that $\tilde{C} < C$ comes from the decrease of off-diagonal rank from (4.12) to (4.5). To summarize, Table 4 shows the key differences between the original RS algorithm and the CBD preconditioner.

**Remark 4.8.** We can fix $D = 2^d$ and employ an FDS as the subdomain solver in the Schwarz preconditioner. Following the analysis above, it is obvious that the associated construct cost is $CN^\alpha/2^{(\alpha-1)d}$. In other words, the cost is higher by at least a factor of $C/\tilde{C}$ than that of the CBD preconditioner.

### 4.4. Asymptotically faster algorithm.

Unlike that in the RS method, the number of DOFs at the last level in the CBD preconditioner depends on only the number of partitions $M$ according to Theorem 4.6. In this section, we show that the construction of the CBD preconditioner can be asymptotically accelerated if we scale $M$ sublinearly to the problem size $N$.

Let us revisit the construction of the CBD preconditioner. In particular, we decompose the factorization cost into two terms: one for the first level and the other for all remaining levels. As previously mentioned, we apply the “compress-then-eliminate” step for $\mathcal{O}(M)$ times at the first level, where computing an ID and the
subsequent elimination both require $O((N/M)^3)$. If we plug in the asymptotic complexities of the RS in Theorem 4.5 for the $O(M)$ DOFs at the second level, we obtain the following:

**Theorem 4.9.** Suppose we apply the RS solver to every subdomain in the CBD preconditioner. Define $P \equiv O(N/M)$. The following complexities holds:

\[ t_f = O\left(P^3M + M^{3(d-1)/d}\right), \quad m_f = t_a = \begin{cases} O\left(P^2M + M \log M\right), & d = 2 \\ O\left(P^2M + M^{4/3}\right), & d = 3 \end{cases} \]

We note that the number of partitions $M$ is a parameter in (4.14), so we can optimize the complexities to obtain asymptotically more efficient methods than the RS solver as the following corollary shows:

**Corollary 4.10.** In 2D, let $M = O(N^{6/7})$, and we have

\[ t_f = O\left(N^{9/7}\right), \quad m_f = t_a = O\left(N^{8/7}\right). \]

In 3D, let $M = O(N^{3/4})$, and we have

\[ t_f = O\left(N^{3/2}\right), \quad m_f = t_a = O\left(N^{5/4}\right), \]

Similarly, we can optimize the memory $m_f$ (or equivalently $t_a$) in (4.14) with respect to $M$. In general, suppose we have an FDS with work complexity $O(N^\alpha)$. Corollary 4.10 can be generalized to the following:

**Theorem 4.11.** Suppose we have an FDS with construction cost $O(N^\alpha)$ when applied to $A$ in (1.2). The optimal complexity to construct the CBD preconditioner employing the FDS as a subdomain solver is

\[ \min_M O\left(P^3M + M^\alpha\right) = O\left(N^{3\alpha/(2+\alpha)}\right) < O\left(N^\alpha\right), \]

where the minimum is obtained when $M = N^{3/(\alpha+2)}$.

5. **Numerical results.** In this section, we benchmark the CBD preconditioner and compare it to the RS factorization [20] on problems in 2D and in 3D. Recall the problem and the domain decompositions in Section 2. The RS solver was applied to solve the global problem (1.2) directly, while the CBD preconditioner employed the RS solver for every subdomain (4 and 8 subdomains in 2D and in 3D, respectively). We fixed $\varepsilon = 1e-3$ in (4.4) as the relative accuracy of low-rank approximations computed with the ID. We used the PCG to solve (1.2), where the matrix-vector (matvec) product with $A$ was carried out via the fast Fourier transform (FFT). In the general case where the discretization grid is non-uniform, the FMM could be used for fast matvec. Below are the notations we used to report results of our experiments (timing and storage are in seconds and in GB, respectively):

- $N$: problem size/matrix size/number of discretization points;
- $M = O(N)$: number of partitions of the problem domain in (2.7);
- $S$: number of DOFs at the last level in the RS solver and that associated with one subproblem in the CBD preconditioner ($2^d$ subproblems in total);

---

3 The radius of the proxy surface used to accelerate the computation of an ID was set to 1.5 as suggested in [20].
• \( t_f \): time of factorization to construct a preconditioner;
• \( m_f \): storage of a preconditioner;
• \( t_s \): time of applying a preconditioner;
• \( t_{pcg} \): total PCG time for solving (1.2) (excluding \( t_f \));
• \( n_{it} \): number of PCG iterations to reach a relative residual of \( 10^{-12} \).

All experiments were performed with MATLAB® R2020a on an Intel Xeon Platinum 8280M2 (“Cascade Lake”) that has 2.1 TB of memory and 112 cores on four sockets (28 cores/socket). Results in Section 5.2 corresponding to solving problems in 2D were obtained using one thread, since intermediate matrices are relatively small that associated computation benefits little from multithreading. Results in Section 5.3 corresponding to solving problems in 3D were obtained using the default multithreading in MATLAB, where the maximum number of computational threads equals to the number of physical cores.

In Section 5.1, we show the convergence of the naïve CBD preconditioner, where subproblems are solved exactly (with round-off errors) without low-rank compression. In Sections 5.2 and 5.3, we show the practical performance of the CBD preconditioner described in Section 4.

5.1. Naïve CBD preconditioner. We benchmarked the number of PCG iterations required by the naïve CBD preconditioner, where subproblems were factorized exactly (with round-off errors) using Cholesky factorization rather than the RS method. For comparison, we fixed the number of subdomains \( D = 2^d \) in the Jacobi preconditioner and the Schwarz preconditioner to be the same as in the CBD preconditioner. Recall that the domain decomposition associated with the block Jacobi preconditioner is non-overlapping but those with the other two preconditioners are overlapping. As Table 5 shows, the number of PCG iterations was almost constant with the two preconditioners based on overlapping domain decompositions. By contrast, the Jacobi preconditioner led to increasing PCG iterations as the problem size increased.

In addition, the number of PCG iterations required by the Schwarz method and the naïve CBD preconditioner were almost the same. For the (practical) CBD preconditioner, we apply the RS method leveraging low-rank compression to every subproblem, which leads to efficient running time and slightly higher PCG iterations. As Remark 4.8 mentioned, we can also apply the RS method to speedup the Schwarz preconditioner, but it will not be as efficient as the (practical) CBD preconditioner.

5.2. Two dimensions. Tables 6a and 6b show results of experiments with a fixed problem size but different numbers of partitions. Observe that \( S \), the number of DOFs at the last level, is almost a constant for the RS method (see (4.13)), whereas \( S = O(M^{1/2}) \) for the CBD preconditioner (Theorem 4.6). Notice that \( S \), a deciding factor of the computational efficiency of both methods, is much smaller with the CBD preconditioner.

Results in Tables 6a and 6b also indicate appropriate \( M \) for the two methods. In Table 6a, results are similar between \( M = 32^2 \) and \( M = 64^2 \); so we chose \( N/M = 64 \) in the RS solver for large problem sizes as done in [20,25]. In Table 6b, \( M = 32^2 \) led to half of the factorization time and the memory footprint than \( M = 16^2 \); so we also chose \( N/M = 64 \) in the CBD preconditioner as well.

Table 7a shows results for solving large problem sizes with the RS method, where the factorization time was always an order of magnitude larger than the PCG time.

(b) CBD preconditioner based on the overlapping domain decomposition (2.10) (four subdomains).

Due to an increasing condition number of the discretized integral operator defined in (2.4), we observe that $S$ increased slower than the predicted $O(N^{1/2})$ scaling; the factorization time $t_f$ scaled slower than the predicted $O(N^{3/2})$ scaling, and the number of PCG iterations $n_{it}$ increased. (This phenomenon is known in [20]; see Table 5.3, 3rd row when $\varepsilon = 1e-3$.) The expected behaviors such as $S = O(N^{1/2})$ can be obtained by employing larger ranks in (4.3) through either decreasing $\varepsilon$ in (4.4) or reducing the radius of the proxy surface. Both require extra computation and would lead to longer factorization time.

To compare with the RS solver, Table 7b shows corresponding results of the CBD preconditioner: (1) The number of DOFs at the last level $S$ (for one subproblem) was much smaller. As a consequence, the factorization time $t_f$ of the CBD preconditioner was an order of magnitude smaller. (2) the storage $m_f$ of the CBD preconditioner was approximately half of that required by the RS solver. On a computer with 2.1...

(b) CBD preconditioner based on the overlapping domain decomposition (2.10) (four subdomains). *PCG stagnated at relative residuals 1.13e−12, 1.71e−12, and 3.99e−12, respectively.

TB memory, the CBD preconditioner could be used to solve problems as large as $N = 16384^2 \approx 2.7 \times 10^8$, for which the RS solver ran out of memory. (3) The CBD preconditioner required more iterations than the RS solver. Overall, the total running time of the CBD preconditioner was approximately a quarter of that taken by the RS solver.

In the CBD preconditioner, $S$, the number of DOFs at the last level, increased as $O(N^{1/2})$ until $N$ reached 16384$^2$, indicating that the ill-conditioning effect associated with the RS solver was mitigated. However, ill-conditioning still affected the convergence of the CBD preconditioner, preventing the PCG from reaching the relative residual $1e−12$ when $N \geq 4096^2$. For environments where many right-hand sides need to be solved, the break-even point of the two preconditioners is $(t_{RS} - t_{CBD}) / (t_{PCG} - t_{RS})$, which evaluates to be about 16 for $N = 8192^2$ in Table 7.

5.3. Three dimensions. We first show results of experiments with a fixed problem size but different numbers of partitions in Tables 8a and 8b. Again, we observe results predicted by (4.13) and Theorem 4.6: $S$ depended on $M$ but not on $N$ in the CBD preconditioner, whereas $S$ was independent of $M$ in the RS method. To solve large problems, we chose $N/M = 8^3 = 512$ for both methods. Notice that this choice for the RS method is different from that in [20] because we used multithreading, which handled large matrices efficiently.

Table 9a shows results of the RS solver for large problem sizes, where the factorization time was at least two orders of magnitude longer than the PCG time.
Table 8: 3D results, where the problem size $N$ is fixed and the number of non-overlapping partitions $M$ varies. The matrix is defined in (2.5).

| $N$ | $M$ | $S$   | $t_f$   | $m_f$   | $t_s$   | $n_{it}$ | $t_{pcg}$ |
|-----|-----|-------|---------|---------|---------|----------|----------|
| $32^3$ | $4^3$ | 5987  | 1.33e+1 | 3.97e-1 | 1.54e-1 | 5        | 8.55e-1  |
| $32^3$ | $8^3$ | 5982  | 1.60e+1 | 3.77e-1 | 1.92e-1 | 5        | 1.04     |
| $32^3$ | $16^3$ | 5990  | 1.83e+1 | 3.78e-1 | 3.65e-1 | 5        | 1.91     |

(a) RS preconditioner based on the domain partitioning (2.7).

| $N$ | $M$ | $S$   | $t_f$   | $m_f$   | $t_s$   | $n_{it}$ | $t_{pcg}$ |
|-----|-----|-------|---------|---------|---------|----------|----------|
| $32^3$ | $4^3$ | 527   | 3.45    | 2.24e-1 | 1.22e-1 | 33       | 4.83     |
| $32^3$ | $8^3$ | 1358  | 1.01e+1 | 2.91e-1 | 1.53e-1 | 32       | 5.19     |
| $32^3$ | $16^3$ | 4120  | 6.17e+1 | 1.65    | 1.02    | 28       | 2.88e+1  |

(b) CBD preconditioner based on the overlapping domain decomposition (2.10) (eight subdomains).

Observe that the numerical results basically match what (4.13) and Theorem 4.5 predict: $S = O(N^{2/3})$, $t_f = O(N^2)$, and $m_f = t_s = O(N^{4/3})$. In addition, the number of PCG iterations was almost constant. It is also clear that the factorization time is prohibitive for a large problem size.

To compare with the RS solver, Table 9b shows results of the CBD preconditioner, where $S$, the number of DOFs at the last level (for one subproblem), was at least an order of magnitude smaller. As a result, the CBD preconditioner required much less factorization time and storage. For example, compare the RS method to the CBD preconditioner for $N = 128^3$: (1) the factorization time of the CBD preconditioner was approximately 50× smaller; (2) the storage of the CBD preconditioner was approximately 7× smaller; and (3) both methods required approximately the same PCG time (CBD took more iterations but every iteration was faster). Empirically, the factorization time and the storage of the CBD preconditioner both scaled closely to $O(N)$. This indicates that the estimates in Theorems 4.6 and 4.7 may be too pessimistic.

For environments where many right-hand sides need to be solved, the break-even point of the two preconditioners is $(t_f^{RS} - t_f^{CBD})/(t_{pcg}^{CBD} - t_{pcg}^{RS})$, which evaluates to be about 13 for $N = 64^3$ and 2500 for $N = 128^3$ in Table 9.

Remark 5.1 (Interface size). It seems intuitive that the smallest eigenvalue will increase when the interface size becomes larger. Numerical experiments on our regular problems support this; see Table 10. However, the benefit of using large interface size, which leads to smaller number of iterations, is usually tiny compared to the extra computational cost for constructing the preconditioner. For results of our new preconditioner reported in the paper, the interface size is $d = 1$, i.e., every extended partition contains only one extra layer of grid points (see Figure 3b). In practice, this choice outperforms larger values of $d$, especially for 3D problems. The reason is that the computation of the ID decomposition in (4.3), a significant portion of the total running time, increases rapidly with $d$, whereas the reduction of iteration numbers is
Table 9: 3D results, where the problem size per partition, i.e., $N/M$, is fixed. The matrix is defined in (2.5).

very small.

6. Conclusions. We introduce the CBD for constructing an overlapping domain decomposition, where the number of subdomains is independent of the problem size, and every subdomain consists of spatially distant regions. The associated CBD (single-level additive Schwarz) preconditioner led to $O(1)$ PCG iterations for solving SPD linear systems, which arises from the discretization of first-kind Fredholm integral equations for Laplace’s equation in 2D and 3D. We apply the RS factorization to construct the CBD preconditioner efficiently, and our numerical results show that the new preconditioner is much more efficient than the original RS method, especially for solving problems in 3D. Two future research directions include

- Incorporating other FDSs for subproblems in the CBD preconditioner. Some candidates include the HIF [20], the RS-S [25, 31], and the IFMM [1, 12, 32], all of which have been shown to achieve quasi-linear complexities (under mild assumptions) for solving problems in both 2D and 3D.
- Extending our approach to solving SPD linear systems arising from machine learning and data science, where the coefficient matrix (a.k.a., kernel matrix)
Table 11: Schwarz preconditioner in 2D: $N/M$ fixed. The matrix is defined in (2.4). (Compare to Table 7.) PCG stagnated at relative residuals $1.31e-12$ and $1.47e-12$, respectively.

| $N$   | $M$   | $t_f$ | $m_f$     | $t_s$   | $n_{it}$ | $t_{pcg}$ |
|-------|-------|-------|-----------|---------|----------|-----------|
| 512$^2$ | 16$^2$ | 9.53  | 1.35      | 6.18e-1 | 46       | 4.14e+1   |

Table 12: Schwarz preconditioner in 3D: $N/M$ fixed. The matrix is defined in (2.5). (Compare to Table 9.)

| $N$   | $M$   | $t_f$ | $m_f$     | $t_s$   | $n_{it}$ | $t_{pcg}$ |
|-------|-------|-------|-----------|---------|----------|-----------|
| 32$^3$ | 4$^3$  | 1.03  | 1.90e-1   | 8.99e-2 | 39       | 4.22      |
| 64$^3$ | 8$^3$  | 8.98  | 1.77      | 8.50e-1 | 52       | 5.72e+1   |
| 128$^3$ | 16$^3$ | 7.76e+1| 1.52e+1  | 8.79    | 82       | 8.84e+2   |
| 256$^3$ | 32$^3$ | 7.48e+2| 1.26e+2  | 1.36e+2 | 156      | 2.62e+4   |

is generated by positive definite functions [35]. When the underlying data set lies in a low-dimensional space [34] or even in a high-dimensional space for some applications [9], the coefficient matrix also has the hierarchical low-rank structure we exploit.

Appendix A. Proof of Theorem 3.7.

Proof. Write $T^{-1}_{Jacobi} A = P_1 + P_2$, where $P_1$ is defined in (3.4). Rewrite (3.7) as

\[(P_1 + P_2)(x_1 + x_2) = \lambda(x_1 + x_2)\]

Applying projections $R_1 R_1^T$ and $R_2 R_2^T$ on both sides, we obatin

\[
\begin{aligned}
P_1 x_2 + P_2 x_1 &= (\lambda - 1)(x_1 + x_2).
\end{aligned}
\]

Lemma 3.5

Applying projections $R_1 R_1^T$ and $R_2 R_2^T$ on both sides, we obatin

\[
\begin{aligned}
P_1 x_2 &= (\lambda - 1)x_1, \\
P_2 x_1 &= (\lambda - 1)x_2.
\end{aligned}
\]

Therefore, we know that

\[
\begin{aligned}
(P_1 + P_2)(x_1 - x_2) &= (x_1 - x_2) + P_2 x_1 - P_1 x_2 \\
&= (x_1 - x_2) - (1 - \lambda)x_2 + (1 - \lambda)x_1 \\
&= (2 - \lambda)(x_1 - x_2).
\end{aligned}
\]

Appendix B. Numerical results for Schwarz preconditioner.

In this section, we show numerical results for the Schwarz preconditioner, where the number of partitions $M = \mathcal{O}(N)$. In Tables 11 and 12, we chose $N/M = 32^2$ and $N/M = 8^3$, respectively, which empirically led to best performance. In this case, the factorization time $t_f$, the storage $m_f$, and the application time of the Schwarz

This manuscript is for review purposes only.
preconditioner $t_s$ all scaled approximately as $O(N)$. However, the number of PCG iterations $n_{it}$ increased rapidly as the problem size increased. As a result, the overall running time of the Schwarz preconditioner exceeded that taken by the CBD preconditioner for large problems: $N \geq 2048^2$ in 2D or $N \geq 128^3$ in 3D (see running time of the CBD preconditioner in Tables 7 and 9).
