Quantum state preparation is an essential ingredient in the realization of quantum technologies such as quantum computing [1], quantum cryptography [2] and other quantum information protocols [3]. A crucial aspect of reliable state preparation is the ability to accurately characterize the state of a quantum system. To this end, quantum state tomography (QST) allows the reconstruction of a state’s density matrix from measurement statistics accumulated through repeated independent measurements of multiple identically-prepared systems [4–6].

In linear-optics, where quantum information is encoded in the polarization of a single photon, different measurement settings are realized with a combination of linear optical elements such as wave plates, beam splitters and polarizing beam splitters, followed by photon counting. QST was first accomplished in such systems by White et al. [7], where the measurement settings corresponded directly to the Stokes’ parameters used to characterize the polarization state of the classical electromagnetic field [8]. Later it was suggested that an over-complete symmetric six-measurement set [9] or an informationally-complete symmetric four-measurement set [9] can be used for improved performance. Other extensions, such as those considering optimal experimental design under realistic technical constraints [11,12], or modifications due to inaccessible information [16,22] or preferable measurements choices [9,11,12,23,30] have also been considered.

To date, all implementations of QST of photonic polarization-encoded qubits have utilized either multiple wave-plates and/or multiple beam splitters per qubit. We propose a technique that uses only one wave plate and two photon-counting detectors per photon mode. As the wave plate rotates, the photon counters measure a pseudo-continuous signal which is then Fourier transformed. The density matrix of the state is reconstructed using the relationship between the Fourier coefficients of the signal and the Stokes’ parameters that represent the state. The experimental complexity, i.e. different wave plate rotation frequencies, scales linearly with the number of qubits.

I. QUANTUM STATE TOMOGRAPHY

Tomography is the process of constructing a representation of an object by imaging it in different sections. In quantum state tomography, we aim to construct a representation of a quantum state \( \hat{\rho} \) from different measurement outcomes. An \( n \)-qubit system is specified by \( 4^n - 1 \) real parameters. We therefore require at least this many outcomes of linearly independent measurements to specify \( \hat{\rho} \).

The probability of obtaining measurement outcome \( j \), given a measurement operator \( \hat{M}_j \), is given by

\[
p_j = \langle \hat{M}_j \rangle = \text{Tr}[\hat{\rho} \hat{M}_j] = \frac{n_j}{N_j},
\]

where \( n_j \) is the number of counts and \( N_j \) is a constant dependent on the detector efficiency and duration of data collection. In a polarization-encoded linear optical system, any projective measurement can be realized with a quarter-wave plate, a half-wave plate and a polarizing beam splitter, as shown in FIG. 1a. A popular choice corresponds to the three Pauli operators.
where \( \hat{\omega} \) is incident on a single wave plate rotating at frequency \( \Omega_m \) followed by a polarizing beam splitter (PBS). Photon counters at the output ports of the PBS continuously measure the intensity, which can be processed to recover Stokes’ parameters. A schematic of this setup is shown in FIG 1 b) for a single qubit and FIG 1 c) for multiple qubits. For multiple qubits, the signal measured is a “coincidence intensity” corresponding to the joint probability of detecting photons at each PBS.

The time-dependent single-qubit projection-valued measure (PVM) associated with the probability of detecting a photon in the horizontal or vertical output modes of each PBS is given by \( \{ \hat{M}_m^H(t), \hat{M}_m^V(t) \} \) where

\[
\hat{M}_m^a(t) = \hat{U}_m^\dagger |a\rangle \langle a| \hat{U}_m, \tag{4}
\]

for \( a = H, V \), where \( m \) labels the qubit mode and

\[
\hat{U}_m(t) = \cos \left( \frac{\beta^2}{2} \right) \hat{\sigma}_0 - i \sin \left( \frac{\beta^2}{2} \right) \hat{v}_m(t) \cdot \hat{\sigma} \tag{5}
\]

is the unitary operator associated with a wave plate in mode \( m \). \( \hat{U}_m(t) \) rotates the operators \( |a\rangle \langle a| \) on the Bloch sphere by an angle \( \beta \), about the vector

\[
\hat{v}_m(t) = \cos(\omega_m t) \hat{k} + \sin(\omega_m t) \hat{i}, \tag{6}
\]

where \( \hat{k} \) and \( \hat{i} \) are unit vectors in Euclidian space (defined by the axes in FIG 2) and \( \hat{v} \cdot \hat{\sigma} = v_1 \hat{\sigma}_x + v_2 \hat{\sigma}_y + v_3 \hat{\sigma}_z \). As the wave plate rotates about the beam-axis at frequency \( \Omega_m \) in real space, \( \hat{v}_m(t) \) rotates about the y-axis in Euclidian space at frequency \( \omega_m = 2\Omega_m \). We assume that the fast axis of the wave plate is aligned at 0 degrees to the horizontal as defined by the polarization of the photons. A phase factor can be included in \( \hat{v}_m(t) \) to account for different initial alignment of the wave plate. The resulting projector \( \hat{M}_m^H(t) \) traces out a figure-8 path on the Bloch sphere, as shown in FIG 2. The retardance of the wave plate determines the size of the figure-8.

To characterize an \( n \)-qubit state, one measures a joint probability of detecting a photon in the \( H \) mode of each PBS. This is given by

\[
p_n(t) = \frac{1}{2^n} \sum_{i_1,\ldots,i_n=0}^3 S_{i_1,\ldots,i_n} \chi_{1,i_1,\ldots,\chi_{n,i_n}}, \tag{7}
\]

where

\[
\chi_{m,i} := \text{Tr}[\hat{\sigma}_i \hat{M}_m^H(t)], \tag{8}
\]
The blue, dashed line shows the EWV for a QWP (\(\beta = \pi/2\)) assesses the noise immunity of the wave-plate. Here we can take on any value other than an integer multiple of \(\pi\). However in practice, some values will be more susceptible to noise than others. We use the equally weighted variance (EWV) \([12]\), which assesses the noise immunity of the wave-plate, to show that \(\beta \approx 11\pi/15\) is most immune to noise, as defined in \([12]\). A plot of the EWV is shown in FIG. 3. Such a retardance will be divided into time bins, with \(N\) coincidence counts in each bin. The number of time bins per period, \(N\), must be at least the Nyquist rate, i.e. twice the highest frequency contained within the signal, to avoid aliasing.

The discrete probability in bin \(\tau_j\) will be given by
\[
p_n(\tau_j) = \frac{n_{H...H}}{N},
\]
where \(N = \sum_{k_1,...,k_n=H,V} n_{k_1,...,k_n}\), \(n\) is the number of qubits and \(n_{k_1,...,k_n}\) is the number of coincidence counts for a given projector \(\hat{M}_{n_1}^{k_1}(t) \otimes \cdots \otimes \hat{M}_{n_2}^{k_2}(t)\).

In practice, \(p_n\) will not be a continuous function of time but rather a discretized approximation. The discretized signal will be divided into time bins, with \(N\) coincidence counts in each bin. The number of time bins per period, \(N\), must be at least the Nyquist rate, i.e. twice the highest frequency contained within the signal, to avoid aliasing.

The discrete probability in bin \(\tau_j\) will be given by
\[
p_n(\tau_j) = \frac{n_{H...H}}{N},
\]
where \(N = \sum_{k_1,...,k_n=H,V} n_{k_1,...,k_n}\), \(n\) is the number of qubits and \(n_{k_1,...,k_n}\) is the number of coincidence counts for a given projector \(\hat{M}_{n_1}^{k_1}(t) \otimes \cdots \otimes \hat{M}_{n_2}^{k_2}(t)\).

In principle, \(\beta\) can take on any value other than an integer multiple of \(\pi\). However in practice, some values will be more susceptible to noise than others. We use the equally weighted variance (EWV) \([12]\), which assesses the noise immunity of the wave-plate, to show that \(\beta \approx 11\pi/15\) is most immune to noise, as defined in \([12]\). A plot of the EWV is shown in FIG. 3. Such a retardance can be achieved with an off-the-shelf wave plate designed for a wave length different to that of the experiment.

In the remainder of this section, we provide specific examples for one- and two-qubit states.

### A. Example: one qubit

For a single qubit, the signal is given by
\[
p_1(t) = \frac{1}{2} \sum_{i=0}^{3} S_i \chi_{1,i}
\]
\[
= \frac{S_0}{2} + \frac{S_1}{2} s^2 \sin(2\omega_1 t) + \frac{S_2}{2} c \sin(\omega_1 t) + \frac{S_3}{2} \left( c^2 + s^2 \cos(2\omega_1 t) \right).
\]
This can be written as

\[ p_1(t) = \frac{a_0}{2} + b_1 \sin (\omega_1 t) + a_2 \cos (2\omega_1 t) + b_2 \sin (2\omega_1 t) , \]  \hspace{1cm} (14)

where the Fourier coefficients are given by

\[ a_0 = S_0 + S_3 c^2 ; \]  \hspace{1cm} (15a)
\[ b_1 = S_2 c s ; \]  \hspace{1cm} (15b)
\[ a_2 = \frac{S_1}{2} s^2 ; \]  \hspace{1cm} (15c)
\[ b_2 = \frac{S_1}{2} s^2 , \]  \hspace{1cm} (15d)

where \( c = \cos(\beta/2) \) and \( s = \sin(\beta/2) \). Linear inversion of Equations (15) gives the Stokes’ parameters in terms of the Fourier coefficients:

\[ S_0 = a_0 - \frac{2a_2 c^2}{s^2} ; \]  \hspace{1cm} (16a)
\[ S_1 = \frac{2b_2}{s^2} ; \]  \hspace{1cm} (16b)
\[ S_2 = \frac{b_1}{c s} ; \]  \hspace{1cm} (16c)
\[ S_3 = \frac{2a_2}{s^2} . \]  \hspace{1cm} (16d)

Substitution into Equation (2), gives the density matrix in terms of the Fourier coefficients:

\[ \rho_1 = \begin{pmatrix} 0.5 & -0.283 - 0.283i \\ -0.283 + 0.283i & 0.5 \end{pmatrix} , \]  \hspace{1cm} (17)

As an example, consider a single-qubit state \( |\psi\rangle_1 \) that has experienced depolarizing noise, characterized by the parameter \( d \), such that

\[ \hat{\rho}_1 = d |\psi\rangle_1 \langle \psi|_1 + (1 - d) \hat{\sigma}_z |\psi\rangle_1 \langle \psi|_1 \hat{\sigma}_z . \]  \hspace{1cm} (18)

Specifically, let’s consider

\[ |\psi\rangle_1 = \frac{1}{\sqrt{2}} (|H\rangle + e^{-i\pi/4}|V\rangle) \]  \hspace{1cm} (19)

and \( d = 0.1 \). A retardance of \( \beta = 11\pi/15 \) produces the signal shown in FIG 4(a). Performing a fast Fourier transform (FFT) of the discretized signal yields the Fourier coefficients in FIG 4(a). The coefficients \( a_f \) and \( b_f \) correspond to the real and imaginary parts of the list generated by the FFT respectively. Inserting the coefficients, \( a_0 = 1, \ b_1 = 0.210, \ a_2 = 0 \) and \( b_2 = -0.236 \) into the density matrix in Equation (17) gives

\[ \rho_1 = \begin{pmatrix} 0.5 & -0.283 - 0.283i \\ -0.283 + 0.283i & 0.5 \end{pmatrix} , \]  \hspace{1cm} (20)

which corresponds to the density operator in Equation (18) for \( d = 0.1 \).  

B. Example: two qubits

For two qubits, the joint probability of detecting a photon in the horizontal output ports of each PBS is given by

\[ p_{21}(t) = \sum_{i_1, i_2=0}^{3} \frac{S_{i_1, i_2}}{4} \chi_{1, i_1} \chi_{2, i_2} \]  \hspace{1cm} (21)
\[ = \frac{a_0}{2} + \sum_{f=1} a_f \cos(\omega_f t) + b_f \sin(\omega_f t) , \]  \hspace{1cm} (22)
where in the second line, we have written the signal in terms of its Fourier coefficients. The extent of the summation depends on the specific choice of relative frequencies, and $\omega'$ are functions of $\omega_1$ and $\omega_2$ from the set \{\omega_1, \omega_2, 2\omega_1, 2\omega_2, \omega_1 \pm \omega_2, \omega_1 \pm 2\omega_2, 2\omega_1 \pm \omega_2, 2\omega_1 \pm 2\omega_2\}. The elements of this set are not necessarily in order of size, and to relate them to $\omega'$, one needs to consider explicit values for $\omega_1$ and $\omega_2$.

As an example, consider the two-qubit state
\[ |\psi\rangle_2 = \frac{1}{\sqrt{2}} (|H\rangle|V\rangle + |R\rangle|L\rangle) . \tag{23} \]

which corresponds to the density operator $\rho_2 = |\psi\rangle_2\langle\psi|_2$ where $|\psi\rangle_2$ is defined in Equation (23). In general, given separable qubits, $p_2$ factorizes into a product of $p_1$ for each qubit.

### III. SUMMARY & CONCLUDING REMARKS

We presented a scheme for performing quantum state tomography of photonic polarization-encoded multi-qubit states. The scheme is simpler than standard tomographic protocols in that only one wave plate and one polarizing beam splitter is required per photon mode.

In this scheme, photon-counting detectors measure a pseudo-continuous time-dependent joint probability as the wave plates rotate at frequency $\Omega_m$. The Fourier coefficients of the signal give the Stokes’ parameters which describe the state. For a single qubit, the optimal wave plate retardance is $\beta \approx 11\pi/15$.

This technique reduces the number of required optical elements and the experimental complexity scales linearly with the number of qubits, in terms of the number of settings required (wave plate rotation frequencies) rather than exponentially, as is the case with QST that uses discrete measurement settings.

An open question is whether the representation of a quantum state as a continuous signal will provide intuitive means for establishing certain properties of the state such as its entanglement.

### IV. ACKNOWLEDGEMENTS

The authors thank Dylan Mahler and Paul Kwiat for helpful discussions. This work was funded by NSERC (USRA) and the DARPA (QuBE) program.

### Appendix A: Probability signal and Fourier coefficients for two-qubit state

In this appendix, we give the probability signal for the specific two-qubit example described in Section II B. We also provide expressions for the Fourier coefficients in terms of the Stokes’ parameters, as well as the inverted expressions for the Stokes’ parameters in terms of the Fourier coefficients.

The signal probability for the state
\[ |\psi\rangle_2 = \frac{1}{\sqrt{2}} (|H\rangle|V\rangle + |R\rangle|L\rangle) , \tag{A1} \]

with a frequency ratio $r = \omega_2/\omega_1 = 5$, is
\[ p_2(t) = \frac{a_0}{2} + b_1 \sin (\omega_1 t) + b_2 \sin (2\omega_1 t) + b_3 \sin (3\omega_1 t) + b_6 \sin (6\omega_1 t) + b_{12} \sin (12\omega_1 t) + a_2 \cos (2\omega_1 t) + a_3 \cos (3\omega_1 t) + a_8 \cos (8\omega_1 t) + a_4 \cos (4\omega_1 t) + a_6 \cos (6\omega_1 t) + a_7 \cos (7\omega_1 t) + a_9 \cos (9\omega_1 t) + a_{10} \cos (10\omega_1 t) + a_{11} \cos (11\omega_1 t) + a_{12} \cos (12\omega_1 t) , \tag{A2} \]
where the Fourier coefficients are

\begin{align*}
    a_0 &= (c^2 (c^2S_{3,3} + S_{0,3} + S_{3,0}) + S_{0,0}) / 2 \\
    a_2 &= s^2 (c^2S_{3,3} + S_{3,0}) / 4 \\
    a_3 &= -a_7 = cs^3S_{1,2} / 4 \\
    a_4 &= -a_6 = c^2s^2S_{2,2} / 2 \\
    a_8 &= s^4 (S_{1,1} + S_{3,3}) / 8 \\
    a_9 &= -a_{11} = cs^3S_{2,1} / 4 \\
    a_{10} &= s^2 (c^2S_{3,3} + S_{0,3}) / 4 \\
    a_{12} &= s^4 (S_{3,3} - S_{1,1}) / 8 ,
\end{align*}

and

\begin{align*}
    b_1 &= cs (c^2S_{2,3} + S_{2,0}) / 2 \\
    b_2 &= s^2 (c^2S_{1,3} + S_{1,0}) / 2 \\
    b_3 &= b_7 = cs^3S_{3,2} / 4 \\
    b_5 &= cs (c^2S_{3,2} + S_{0,2}) / 2 \\
    b_8 &= s^4 (S_{3,1} - S_{1,3}) / 8 \\
    b_9 &= -b_{11} = -cs^3S_{2,3} / 4 \\
    b_{10} &= s^2 (c^2S_{3,1} + S_{0,1}) / 4 \\
    b_{12} &= s^4 (S_{1,3} + S_{3,1}) / 8 ,
\end{align*}

where \( c = \cos(\beta / 2) \) and \( s = \sin(\beta / 2) \). Inverting Equations (A3) and (A4) gives

\begin{align*}
    S_{0,0} &= 4c^2 \left( (a_8 + a_{12}) c^2 - (a_2 + a_{10}) s^2 \right) / s^4 + 2a_0 \\
    S_{0,1} &= -4 \left( (b_8 + b_{12}) c^2 - b_{10}s^2 \right) / s^4 \\
    S_{0,2} &= 2b_5 / cs - 4b_3c / s^3 \\
    S_{0,3} &= 4a_{10} / s^2 - 4(a_8 + a_{12}) c^2 / s^4 \\
    S_{1,0} &= 4 \left( (b_8 - b_{12}) c^2 + b_2s^2 \right) / s^4 \\
    S_{1,1} &= 4 \left( a_8 - a_{12} \right) / s^4 \\
    S_{1,2} &= 4a_3 / cs^3 \\
    S_{1,3} &= -4 \left( b_8 - b_{12} \right) / s^4 \\
    S_{2,0} &= 4b_9c / s^3 + 2b_1 / cs \\
    S_{2,1} &= 4a_9 / cs^3 \\
    S_{2,2} &= 2a_4 / c^2s^2 \\
    S_{2,3} &= -4b_9 / cs^3 \\
    S_{3,0} &= 4a_2 / s^2 - 4(a_8 + a_{12}) c^2 / s^4 \\
    S_{3,1} &= 4 \left( b_8 + b_{12} \right) / s^4 \\
    S_{3,2} &= 4b_3 / cs^3 \\
    S_{3,3} &= 4 \left( a_8 + a_{12} \right) / s^4 .
\end{align*}

Substituting the Stokes’ parameters, along with the Fourier coefficients in FIG 4 b), into Equation (2), gives the reconstructed density matrix in Equation (24) which corresponds to the density operator \( \hat{\rho}_2 = |\psi\rangle_2 \langle \psi|_2 \) where \( |\psi\rangle_2 \) is defined in Equation (A1).
