Abstract. We briefly review the theory for electromagnetic reactions in light nuclei based on the coupled-cluster formulation of the Lorentz integral transform method. Results on photodisintegration reactions of 22O and 40Ca are reported on and preliminary calculations on the Coulomb sum rule for 4He are discussed.

1 Introduction

The investigation of nuclear reactions from first principles is fundamental in bridging nuclear physics with the underlying quantum chromo-dynamics regime. Nuclear reactions induced by electromagnetic probes are very useful as the electromagnetic current is well known and a clean comparison with experimental data can be performed [1]. Nowadays this valuable information is not only accessible for the lightest nuclei, but novel theoretical approaches are being developed to tackle nuclei with a larger number of nucleons. Below, we briefly review the Lorentz integral transform (LIT) approach in its coupled-cluster (CC) theory formulation [4]. Thereafter, we discuss some recent results regarding photoabsorption and electron-scattering reactions.

2 Theoretical Formulation

The key ingredient to study reactions induced by electromagnetic external probes, like photons or electrons, is the nuclear response function

\[ R(\omega, q) = \sum_n |\langle n | O(q) | 0 \rangle|^2 \delta (E_n - E_0 - \omega), \]  

where \( O(q) \) is the excitation operator, which will depend specifically on the external probe and on the momentum-transfer \( q \). The nuclear response function is a dynamical observables which requires knowledge on the whole spectrum of the nucleus, being \( |0 \rangle \) and \( |n \rangle \) the ground- and excited-state, respectively. The exact solutions of the many-body problem for the excited-states, typically in the

---

a e-mail: bacca@triumf.ca
continuum, is limited in mass number and in energy $\omega$. In particular, it is difficult to calculate when many channels are open. However, one can use the LIT approach [2] to reduce the continuum problem to the solution of a bound-state equation. In particular, recently this method was reformulated using coupled-cluster theory [5], obtaining a new approach to extend ab-initio studies of electromagnetic observables to heavier and neutron-rich nuclei [3, 4].

In coupled-cluster theory one introduces the similarity transformed Hamiltonian

$$\tilde{H} = \exp(-T)H_0 \exp(T),$$  \hspace{1cm} (2)

where $H_0$ is normal-ordered with respect to a chosen Slater determinant $|\Phi_0\rangle$. Correlations are introduced through the cluster operator $T$ which is expanded into particle-hole $(ph)$ excitation operators, i.e., $T = T_1 + T_2 + \ldots$, with the 1$p$-1$h$ excitation operator $T_1$, the 2$p$-2$h$ excitation operator $T_2$, and so on. In the coupled-cluster formalism [4] the response function in Eq. (1) becomes

$$R(\omega, q) = \sum_n \langle 0_L|\tilde{O}^+(q)|n_R\rangle\langle n_L|\tilde{O}(q)|0_R\rangle \delta(E_n - E_0 - \omega),$$  \hspace{1cm} (3)

where $\tilde{O}^+(q) = e^{-\hat{T}}O^+(q)e^{\hat{T}}$ is the similarity transformed (adjoint) excitation operator and $\langle 0_L|$, $|0_R\rangle$, $\langle n_L|$, $|n_R\rangle$ are the left and right reference ground-states (excited-states), respectively (see also Ref. [6]). The utilization of the LIT method requires to find the solution $\tilde{\Psi}_R$ of the following bound-state equation [3, 4]

$$(\tilde{H} - \Delta E_0)|\tilde{\Psi}_R\rangle = \tilde{\Psi}(q)|0_R\rangle,$$  \hspace{1cm} (4)

where $\Delta E_0$ is the ground-state correlation energy and $|0_R\rangle = |\Phi_0\rangle$. By assuming that $\tilde{\Psi}_R = R|\Phi_0\rangle$ and expanding $R$ in $ph$ excitation operators, similarly to what done with $T$, one can see that Eq. (4) is equivalent to an equation-of-motion [5] with a source in the right-hand-side. In Ref. [3, 4] we have implemented this method with a truncation of both the operators $T$ and $R$ up to the 2$p$-2$h$ excitation level, namely up to single and double (SD) excitations. Such a scheme is being named here the LIT-CCSD method.

By solving Eq. (4) one finds the LIT of the response function, integrated from threshold $\omega_{th}$ to infinity

$$L(\omega_0, \Gamma) = \frac{\Gamma}{\pi} \int_{\omega_0}^{\omega_{th}} d\omega \frac{R(\omega, q)}{(\omega - \omega_0)^2 + \Gamma^2} = \langle \tilde{\Psi}_L|\tilde{\Psi}_R\rangle,$$  \hspace{1cm} (5)

where $\omega_0$ and $\Gamma$ are auxiliary parameters and $\langle \tilde{\Psi}_L\rangle$ is the solution of the equivalent to Eq. (4) for the left-hand-side. To obtain the response function $R(\omega, q)$ we then invert Eq. (5) using the method outlined in Refs. [7, 8], which looks for the regularized solution of the integral transform equation.

Below we highlight some of our recent calculations obtained for photoabsorption and electron scattering reactions using as only ingredient an Hamiltonian $H$ that contains, besides kinetic energy, a two-nucleon force derived in chiral effective field theory at next-to-next-to-next-to-leading (N$^3$LO) order [11].

3 Photodisintegration reactions

Photodisintegration reactions have been widely studied in the ’70s with experiments on a variety of stable nuclei. The main observed feature of the measured cross sections was a very pronounced peak, referred to as the giant dipole resonance, located at excitation energies of about 10–30 MeV. First theoretical interpretations were given in terms of collective models [9, 10] and until very recently, most microscopic calculations were obtained in terms of phenomenological approaches and interactions,
Figure 1. $^{22}$O photodisintegration cross section compared with data from Ref. [15]. The curve is calculated with the $N^3$LO nucleon-nucleon force and is shifted to the experimental threshold.

Figure 2. $^{40}$Ca photodisintegration cross section compared to data from Ref. [14]. The curve is calculated with the $N^3$LO nucleon-nucleon force and is shifted to the experimental threshold.

see, e.g., Ref. [12]. The LIT-CCSD approach introduced above, offers the opportunity to investigate photodisintegration reactions from an ab-initio point of view using nucleon-nucleon potentials, which reproduce two-nucleon scattering data [11]. Moreover, it allows one to study equivalent processes in neutron-rich nuclei, which have been more recently investigated with Coulomb excitations experiments at the rare isotope facilities, see e.g. Ref. [15].

In the long-wavelength limit, the photodisintegration cross section can be written as

$$\sigma_\gamma(\omega) = 4\pi^2 \alpha \omega R^D(\omega),$$

where $\alpha$ is the electromagnetic coupling constant and $R^D(\omega)$ is the dipole response function, namely Eq. (1) with the dipole operator as excitation operator

$$D_z = \sum_k^A (z_k - Z_{cm}) \left( 1 + \tau_3^k \right).$$

Here, $z_k$ is the $z$-coordinate of the $k$-th nucleon in the lab-frame, while $Z_{cm}$ denotes the $z$-component of the center of mass of the nucleus and $\tau_3^k$ is the third component of the isospin of the $k$-th nucleon.

In Refs. [3,4] we implemented the one-body operator of Eq. (7) in the solution of Eq. (4) and investigated the photodisintegration of a variety of light and medium-mass nuclei. After having benchmarked the LIT-CCSD method with exact hyperspherical harmonics [13] on $^4$He, where we have observed that higher-order corrections to the $T$ and $R$ operator are very small, we have proceeded to study heavier nuclei. In particularly, here we review our results for the neutron-rich $^{22}$O isotope in Fig. 1 and the stable $^{40}$Ca nucleus in Fig. 2.

For $^{22}$O one notices the appearance of a small peak at low energy, also named pigmy dipole resonance and experimentally observed in a variety of neutron-rich nuclei, which agrees very nicely with data from Leistenschneider et al. [15]. It is worth noticing that nothing in the interaction has been adjusted to $^{22}$O and that no cluster structure has been imposed a priori in the calculation. This is not the first time that the LIT approach suggests the existence of a low-energy dipole mode, as in Ref. [16] a similar situation was found in $^6$He.
Because the computational cost of the coupled-cluster method scales mildly with respect to the mass number, we can extend our studies to the photonuclear cross-section of $^{40}$Ca. Fig. 2 shows a comparison of the LIT-CCSD calculations with data by Ahrens et al. [14]. We clearly see a giant resonance, even though the theoretical prediction is slightly broader and lower in strength. Both in Fig. 1 and Fig. 2 the band in the curve is obtained by inverting LIT with different $\Gamma$ parameters in Eq. (5) and can be seen as a lower estimate of the theoretical error bar.

4 Electron-scattering reactions: Coulomb sum rule

Electron scattering reactions have been already investigated within the LIT method, see, e.g., [17]. With the objective in mind to eventually tackle neutrino-nucleus interactions relevant for long-baseline neutrino experiments, we initiated a study of electron-scattering reactions within coupled-cluster theory. The latter has in fact the potential to be applied to $^{16}$O and other medium-mass nuclei, which are used as detector materials in neutrino experiments. Following the work done with the Green’s function Monte Carlo method in Ref. [18], we will first investigate the Coulomb sum rule.

The longitudinal Coulomb sum rule (CSR) is defined as

$$S_L(q) = \frac{1}{Z} \int_{\omega_0}^{\infty} d\omega \frac{R_L(\omega, q)}{G_E^2(Q^2)},$$

(8)

where $R_L(\omega, q)$ is the longitudinal response function, i.e., Eq. (1) with $O(q) = \rho(q)$ and a recoil term $\frac{q^2}{2M}$ in the delta function, while $G_E^p(Q^2)$ is the proton electric form factor as a function of the square of the four-momentum $Q^2$. The charge operator can be written as

$$\rho(q) = \sum_k A_k \left( \frac{1 + \tau_k}{2} G_E^p(Q^2) + \frac{1 - \tau_k}{2} G_E^n(Q^2) \right) e^{iqz},$$

(9)

with $G_E^n(Q^2)$ being the neutron electric form factor. Similarly to what done in Ref. [17] we perform a multipole expansion of Eq. (9) in terms of Coulomb multipoles, separating isoscalar ($s$) and isovector ($v$) contributions as

$$\rho(q) = \sum J \left( C_j^s(q) + C_j^v(q) \right).$$

(10)
Each of the Coulomb multipole is calculated separately solving Eq. (4) for various fixed values of the momentum transfer $q$. Below, we show LIT-CCSD results for $^4$He obtained using the N$^3$LO nucleon-nucleon chiral interaction.

In Fig. 5 we test the convergence of our calculations in terms of the model space size $N_{\text{max}} = 2n + l$, determined by the number of single-particle shells used in the $ph$ expansion. For the isovector monopole $C^v_0$ and isovector dipole $C^v_1$ operator, one observes that very good convergence is reached already for $N_{\text{max}} = 14$. For higher order multipoles, slightly larger model spaces are needed. With respect to exact hyperspherical harmonics [13], $C^v_1$ calculations from coupled-cluster theory agree very nicely up to about $q = 200$ MeV/c, but are 20% smaller at higher momenta. Note that at energies of about 300 MeV and higher, the chiral interaction of Ref. [11] is at the limit of its applicability. Work is in progress to understand the role of center of mass contamination in our calculation, given that the operator in Eq. (9) is not translational invariant.

In Fig. 4 we compare the recursive sum of the isovector multipoles that make up the CSR. One can readily see that, while at momentum transfer below $q = 100$ MeV/c two or three multipoles suffice, at the highest momentum transfer considered $q = 500$ MeV/c, nine multipoles need to be calculated before reaching convergence. A similar situation is found for the isoscalar multipoles. Finally, in Fig. 5 we compare the total CSR calculated from coupled-cluster theory with experimental data. Our calculation still misses the contribution of the isoscalar monopole term. Measurements of the longitudinal response functions at intermediate momentum transfer have been performed in the past and are collected in Ref. [19], while low momentum data at $q = 200$ and 250 MeV/c are taken from Buki et. al. [20]. Since finite maximal values of the energy transfer $\omega_{\text{max}}$ are measured in experimental data, the experimental CSR is obtained as

$$S_L(q) = \frac{1}{Z} \int_{\omega_{\text{th}}}^{\omega_{\text{max}}} d\omega \frac{R_L(\omega, q)}{G^p_E(Q^2)} + S_L, \text{tail}$$

(11)

where $S_L, \text{tail}$ is taken from the theoretical calculations of $^4$He response functions of Ref. [17]. As shown in Fig. 5 our calculation agrees well with the experimental data from low- to intermediate-momenta. It is known from Ref. [17] that three-body forces are not very pronounced on the CSR at the values of momentum transfer where data are available. Work is being presently directed to benchmark these studies with hyperspherical harmonics, with the prospect of tackling $^{16}$O.
5 Conclusions

After a short review of the coupled-cluster formulation of LIT method, we report on our recent calculations of the photodisintegration of the neutron-rich $^{22}$O nucleus and the stable $^{40}$Ca medium-mass nucleus. We then show our preliminary calculation of the Coulomb sum rule for $^4$He, which describe rather well the available experimental data. A benchmark with data is essential for any theory that is going to be used to model the neutrino-nucleus interaction taking place within the detectors of neutrino long-baseline experiments. Using the LIT-CCSD theory, our long term goal is to study neutrino scattering off $^{16}$O, which is relevant for the T2K experiment.
