Neutral-pion, $\pi^0$, spectra were measured at midrapidity ($|y| < 0.35$) in Au+Au collisions at $\sqrt{s_{NN}} = 39$ and 62.4 GeV and compared to earlier measurements at 200 GeV in the $1 < p_T < 10$ GeV/c transverse-momentum ($p_T$) range. The high-$p_T$ tail is well described by a power law in all cases and the powers decrease significantly with decreasing center-of-mass energy. The change of powers is very similar to that observed in the corresponding $p+p$-collision spectra. The nuclear-modification factors ($R_{AA}$) show significant suppression and a distinct energy dependence at moderate $p_T$ in central collisions. At high $p_T$, $R_{AA}$ is similar for 62.4 and 200 GeV at all centralities. Perturbative-quantum-chromodynamics calculations that describe $R_{AA}$ well at 200 GeV, fail to describe the 39 GeV data, raising the possibility that the relative importance of initial-state effects and soft processes increases at lower energies. A conclusion that the region where hard processes are dominant is reached only at higher $p_T$, is also supported by the $x_T$ dependence of the $x_T$-scaling power-law exponent.

PACS numbers: 25.75.Dw

Large transverse-momentum ($p_T$) particles produced in high-energy nucleus-nucleus (AB) collisions play a crucial role in studying the properties of the medium created in relativistic heavy-ion collisions. Most hadrons at sufficiently high $p_T$ are fragmentation products of hard-scattered partons and their production rate in vacuum, as measured in $p+p$ collisions, is well described by perturbative quantum chromodynamics (pQCD) [1]. In the absence of any nuclear effects the production rate in relativistic heavy-ion collisions in the pQCD regime, i.e., at sufficiently high $p_T$, would scale with the increased probability that a hard scattering occurs, due to the large number of nucleons. This probability is characterized by the nuclear thickness function $T_{AB}$ [2]. However, such scaling has been violated to various degrees depending both on collision energy, $\sqrt{s_{NN}}$, and hadron $p_T$. At lower collision energies, the hadron yield is enhanced above the expected scaling. This was first observed in $p+A$ and this enhancement is generally attributed to multiple soft scattering ("Cronin effect" [2]), and is presumed to occur in ion-ion collisions as well. Initial parton distribution functions in nuclei (nPDF) are different from those in protons [4].

Finally, if a dense, colored medium is formed in the AB collision, the hard-scattered parton may traverse some of it, losing energy in the process. Therefore, the observed yield at a given (high) $p_T$ will be lower than that expected from $T_{AB}$ scaling, exhibiting "suppression" or "jet quenching," described in terms of the nuclear-modification factor, $R_{AA}$ (see Eq. (1)). Alternatively, other studies divide the yields for heavy-ion collisions at one energy with those for the same colliding species at a lower energy Au+Au, rather than scaled $p+p$ reference data, to study energy and centrality scaling [5].

One of the first discoveries at the Relativistic Heavy-Ion Collider (RHIC) was a very large hadron suppression at high $p_T$ (above $\sim 3$ GeV/c) in $\sqrt{s_{NN}} = 130$ and 200 GeV Au+Au collisions [6,7]. This suppression was attributed to the dominance of parton energy loss in the medium, i.e., to final state effects. To test this hypothesis, the same measurements were performed in $d+$Au collisions [10], where the formation of the hot, dense partonic medium is not expected, and initial-state effects (if any) prevail. No suppression in $d+$Au data was observed leaving little (if any) room for the initial-state effects as the origin of the large jet quenching observed in Au+Au. Studies with the lighter Cu+Cu system at three energies ($\sqrt{s_{NN}} = 22.4$, 62.4 and 200 GeV [11]) have revealed that at $\sqrt{s_{NN}} = 22.4$ GeV mechanisms that enhance $R_{AA}$ ($> 1$) dominate at all centralities. Note, however, that this data set had very limited $p_T$ range ($p_T < 4$ GeV/c). At 62.4 GeV, jet quenching overwhelms any enhancement and leads to a suppression ($R_{AA} < 1$) in more central collisions.

The low-energy scan at RHIC provides an opportunity to study the transition from enhancement ($R_{AA} > 1$) to suppression ($R_{AA} < 1$) and the evolution of $R_{AA}$ with collision energy, centrality and $p_T$. The results put constraints on energy-loss models (see [12] and references therein).

Here, we present new measurements by the PHENIX experiment at RHIC of $\pi^0$ invariant yields and $R_{AA}$ in Au + Au collisions at $\sqrt{s_{NN}} = 39$ and 62.4 GeV. The data were taken during the 2010 run and the $p_T$ limits (statistics) were 8 GeV/c and 10 GeV/c, respectively. Reference $p+p$-collision data for $\sqrt{s_{NN}} = 62.4$ GeV were taken in the same experiment in the 2006 run [1], while for $\sqrt{s_{NN}} = 39$ GeV, data measured in the FERMILAB experiment E706 were used [13].

Neutral pions were measured on a statistical basis via their $\pi^0 \rightarrow \gamma \gamma$ decay branch with the electromagnetic calorimeter (EMCal) [14]. The EMCal comprises two calorimeter types: 6 sectors of lead scintillator sampling calorimeter (PbSc) and 2 sectors of lead glass Cerenkov calorimeter (PbGl). Each sector is located $\pm 5$ m from the beaml ine and subtends $|y| < 0.35$ in pseudorapidity and $\Delta \phi = 22.5^\circ$ in azimuth. This Letter presents results obtained with the PbSc sectors only. The segmentation of the PbSc ($\Delta \eta \times \Delta \phi = 0.01 \times 0.01$) ensures that the two photons from the $\pi^0 \rightarrow \gamma \gamma$ decays are very well resolved.
up to \( p_T < 12 \text{ GeV/c} \), i.e. across the entire \( p_T \) range of this measurement.

The results are based on data sets of \( 3.5 \cdot 10^8 \) and \( 7.0 \cdot 10^8 \) minimum bias \( \text{Au} + \text{Au} \) events at 39 and 62.4 GeV, respectively. The minimum bias (MB) trigger for both \( \sqrt{s_{\text{NN}}} = 39 \) and 62.4 GeV was provided by the Beam-Beam-Counters (BBC) \([2]\), located close to the beam axis in both directions and covering \( 3.0 \leq |\eta| \leq 3.9 \). In order to reduce background at least two hits were required in both BBC’s. This condition selects \( \sim 86\% \) of the total inelastic cross section. The centrality selection in \( \text{Au} + \text{Au} \) collisions at both energies was based on the charged signal sum of the BBC’s, which is proportional to the charged particle multiplicity. For each centrality the average number of binary collisions \((\langle N_{\text{coll}} \rangle)\) and the number of participants \((\langle N_{\text{part}} \rangle)\) were calculated using a Glauber model \([2]\) based Monte Carlo code.

### TABLE I: Sources of systematic uncertainties and their relative effect (in \%) on the invariant yields

| \( p_T \) energy | \( 2 \text{ GeV/c} \) | \( 5 \text{ GeV/c} \) | Type   |
|------------------|------------------|------------------|-------|
| \( \text{39 GeV (62.4 GeV)} \) |                   |                  |       |
| Yield extraction | 3\% (3\%)        | 3\% (3\%)        | A     |
| PID efficiency   | 4.5\% (4.5\%)    | 4.5\% (4.5\%)    | B     |
| Energy scale     | 10.5\% (8.0\%)   | 14.5\% (10.0\%)  | B     |
| Acceptance       | 2\% (2\%)        | 2\% (2\%)        | B     |
| Conversion       | 4\% (4\%)        | 4\% (4\%)        | B     |
| Off vertex       | 1.5\% (1.5\%)    | 1.5\% (1.5\%)    | C     |
| Total for \( \pi^0 \) yields | 12.7\% (10.7\%) | 16.2\% (12.3\%) |       |

The PHENIX analysis of neutral pions is described in detail elsewhere \([9]\). Table I lists the sources of systematic uncertainties on the extracted-\( \pi^0 \) invariant yields in this analysis. They can be divided into three different categories: (1) Type-A, \( p_T \)-uncorrelated; (2) Type-B, \( p_T \)-correlated, where the correlation may be an arbitrary smooth function; (3) Type-C, \( p_T \)-correlated, where all points move by the same fraction up or down. The main sources of systematic uncertainties in the \( \pi^0 \) measurement are the energy scale, yield extraction and particle-identification (PID) efficiency correction.

Figure 1 shows the invariant yields of the \( \pi^0 \) s for all centralities and also in minimum bias collisions. From fitting the \( \sqrt{s_{\text{NN}}} = 39 \) and 62.4 GeV minimum bias spectra with a power law function \((x \, p_T^2)\) for \( p_T > 4 \text{ GeV/c} \), we obtained powers \( n_{39} = -13.04 \pm 0.08 \) and \( n_{62.4} = -10.60 \pm 0.03 \), respectively, significantly steeper than at \( \sqrt{s_{\text{NN}}} = 200 \text{ GeV} \), where \( n_{200} = -8.06 \pm 0.01 \) for MB collisions \([4]\). The slopes of the corresponding \( p+p \) collision spectra are somewhat different, but comparable, \( n_{39}^{pp} = -13.59 \pm 0.21 \), \( n_{62.4}^{pp} = -9.82 \pm 0.18 \) and \( n_{200}^{pp} = -8.22 \pm 0.09 \), respectively.

Nuclear effects on the \( \pi^0 \) production are quantified using the nuclear modification factor

\[
R_{\text{AA}}(p_T) = \frac{1/(N_{\text{AA}}^\text{evt})d^2N_{\text{AA}}^{\pi^0}}{(T_{\text{AB}}) \times d^2\sigma_{pp}^{\text{NN}}/dp_Tdy},
\]

where \( \sigma_{pp}^{\text{NN}} \) is the production cross section of \( \pi^0 \) in \( p+p \) collisions, and \( (T_{\text{AB}}) = \langle N_{\text{coll}} \rangle / \sigma_{pp}^{\text{NN}} \) is the nuclear thickness function averaged over the range of impact parameters contributing to the given centrality class according to the Glauber model. Thus \( R_{\text{AA}} \) compares the yield observed in \( A + A \) collisions to the yield expected from the superposition of \( N_{\text{coll}} \) independent \( p+p \) interactions. In the absence of nuclear effects, \( R_{\text{AA}} \) should be equal to unity. However, \( R_{\text{AA}} \approx 1 \) does not necessarily imply the absence of suppression, it may also indicate a balance between enhancing and depleting mechanisms.

In order to calculate \( R_{\text{AA}} \), a reference \( p_T \) distribution in \( p+p \) collisions is needed. Preferably this is measured with the same detector, in which case many systematic uncertainties cancel in the ratio. The PHENIX experiment has measured the \( \pi^0 \) cross section in \( p+p \) collisions at \( \sqrt{s_{\text{NN}}} = 62.4 \text{ GeV} \) \([3]\) but only up to \( p_T = 7 \text{ GeV/c} \) while the current Au+Au measurement reaches up to \( 10 \text{ GeV/c} \). Hence the \( p+p \) data were fitted with a power law function between 4.5 \( < p_T \) \( < 7 \text{ GeV/c} \) and then extrapolated. The systematic uncertainty resulting from this extrapolation reaches 20\% at 10 GeV/c, estimated from a series of fits, where each time one or more randomly selected points are omitted and the remaining points are re-fitted.

So far PHENIX has not measured the \( p+p \) spectrum of \( \pi^0 \) at \( \sqrt{s_{\text{NN}}} = 39 \text{ GeV} \). Therefore, data from the Fermilab experiment E706 \([13]\) were used. However, the E706 acceptance \((-1 < |\eta| < 0.5\) is different from that of PHENIX \((|\eta| < 0.35\), and since \( dN/d\eta \) is not flat, a \( p_T \)-dependent correction was applied to the E706 data. This correction factor was determined from a PYTHIA simulation by means of the ratio of yields (normalized per unit rapidity) when calculated from the observed yield in the
PHENIX and E706 acceptance windows. The systematic uncertainty of the correction is 1–2% at 3 GeV/c but reaches 20% at 8 GeV/c.

**FIG. 2:** (Color online) Nuclear modification factor $R_{AA}$ of $\pi^{0}$ in Au + Au collisions in most central 0–10% (a) and mid-peripheral 40–60% (b). Error bars are the quadratic sum of statistical and $p_{T}$-correlated systematic uncertainties (including systematic uncertainties from the $p+p$-collision reference). Boxes around 1 are the quadratic sum of the C-type uncertainties combined with the $N_{\text{coll}}$ uncertainties. These are fully correlated between different energies. Also shown for central collisions are pQCD calculations with regular Cronin-effect (solid lines) and with the Cronin-effect reduced by a factor of two for all three energies (bands).

Figure 2 shows the nuclear modification factor of $\pi^{0}$'s measured in Au + Au collisions at $\sqrt{s_{NN}}$ = 39, 62.4 and 200 GeV (data from [9]) as a function of $p_{T}$ for most central collisions (a) and 40–60% centrality (b). In the most central collisions (0–10%) there is a significant suppression for all three energies, while in mid-peripheral collisions (40–60%) at $\sqrt{s_{NN}}$ = 39 GeV, $R_{AA}$ is consistent with unity above $p_{T}$ > 3 GeV/c.

For 0–10% pQCD calculations [16, 17] are also shown. The solid curves are calculated with the same parametrization that was successful for 200 GeV Au + Au data (and also 200 GeV Cu + Cu [11]). Neither the 62.4, nor the 39 GeV data are consistent with the predictions. The only qualitative agreement is that the turnover point of the $R_{AA}$ curves moves to higher $p_{T}$ with lower collision energy as observed in the data. The bands are calculated within the same framework but with the Cronin-effect reduced and the energy loss varied by ±10%. The 200 GeV data are still well described, the 62.4 GeV data are consistent within uncertainties, but the 39 GeV $R_{AA}$, particularly the shape, is inconsistent with the corresponding band.

Coupled with the observations that the slopes at high $p_{T}$ become much steeper, but the bulk properties (like elliptic flow, energy density, apparent temperature) change only slowly in the collision energy range in question, it is quite conceivable that hard scattering as a source of particles at a given $p_{T}$ becomes completely dominant only at higher transverse momentum, i.e. jet quenching will be “masked” up to higher $p_{T}$. Note that while the shapes at lower $p_{T}$ are different, at $p_{T}$ ≳ 7 GeV/c $R_{AA}$ is essentially the same for the 62.4 and 200 GeV data, irrespective of centrality (see also Fig. 3). While in the 39 GeV data $R_{AA}$ also shows a decreasing trend at higher $p_{T}$, unfortunately the $p_{T}$ reach of the current data sample precludes any conclusion as to what would happen to their $R_{AA}$ at even higher $p_{T}$.

![Image](image_url)

**FIG. 3:** (Color online) Nuclear modification factor averaged for $p_{T}$ > 6 GeV/c. Uncertainties are shown as error bars (statistical), boxes (sum of $p_{T}$-uncorrelated and $N_{\text{coll}}$), boxes around one (Type B and C and uncertainties from the $p+p$-collision reference).

Figure 3 shows $p_{T}$-averaged $R_{AA}$ as a function of the number of participants. The averaging was done above $p_{T}$ > 6 GeV/c. Our first observation is that $R_{AA}$ decreases with increasing centrality even for the lowest-energy system. Similarly, as already discussed in the context of Fig. 2 at high enough $p_{T}$ the suppression is the same at 62.4 and 200 GeV, at all centralities. This is remarkable because the power $n$ of the fit to the spectra changes approximately by two units from 200 to 62.4 GeV, so the average momentum loss of the partons also has to be different in order to compensate the effect of the changing slope. The average momentum loss is usually defined by the fractional momentum shift $\delta p_{T}/p_{T}$ between the corresponding Au + Au and $T_{AA}$-scaled $p+p$ spectra as follows. Since the power law tails of the $p+p$ and Au + Au spectra are similar, they can be fitted simultaneously with the same function and same power $n$

$$f(p_{T}) = \frac{A}{(p_{T}(1+\delta p_{T}/p_{T}))^{n}}$$

with $\delta p_{T}$ being the horizontal shift between the scaled $p+p$ and the Au + Au spectra. In panel (a) of Fig. 4 the observed fractional momentum shifts are shown for central collisions, as a function of the Au + Au $p_{T}$.

Inclusive single-particle spectra at sufficiently high $p_{T}$ and collision energy were predicted to exhibit scaling with the variable $x_{T} = 2p_{T}/\sqrt{s}$ such that the produc-
to the rise observed in the low-x region of the data. It may not even reach its maximum in the soft processes [20], while at higher energies is then calculated as

\[ n_{\text{eff}}(x_T) = \frac{\log(Yield(x_T,\sqrt{s_1})/Yield(x_T,\sqrt{s_2}))}{\log(\sqrt{s_2}/\sqrt{s_1})} \]  

(4)

In panel (b) of Fig. 4, \( n_{\text{eff}}(x_T) \) is shown when comparing invariant-\( \pi^0 \) yields in \( p+p \) and \( Au+Au \) collisions at different energies. Both the shape and the magnitude of \( n_{\text{eff}}(x_T) \) is similar for the 62.4/200GeV \( p+p \) and \( Au+Au \) as well as for the 39/200GeV \( p+p \) data. The rise of \( n_{\text{eff}}(x_T) \) at lower \( x_T \) can be attributed to the dominance of soft processes [20], while at higher \( x_T \) they deviate strongly from leading-twist scaling predictions [14, 21]. However, the shape of \( n_{\text{eff}}(x_T) \) in the 39 and 200GeV \( Au+Au \) comparison is very different from all others. It may not even reach its maximum in the measured \( x_T \) range, and its constant rise is similar to the rise observed in the low-\( x_T \) (soft) region of the other data shown. One possible explanation could be that while present, hard scattering is still not the overwhelming source of high-\( p_T \) \( \pi^0 \) in the currently available \( p_T \) range in 39 GeV \( Au+Au \) collisions.

In summary, the \( \pi^0 p_T \) spectra were measured in \( Au+Au \) collisions at two different energies, \( \sqrt{s_{NN}} = 39 \) and 62.4GeV, and compared to the earlier result for \( \sqrt{s_{NN}} = 200 \)GeV. In all cases the high \( p_T \) part of the invariant yields can be well described with a single power law function. The powers decrease considerably at lower \( \sqrt{s_{NN}} \), and since the soft processes change only slowly with collision energy, jet quenching might be “masked” up to higher transverse momenta. The high-\( p_T \) \( \pi^0 \) yields in \( Au+Au \) at 62.4GeV are suppressed, and above \( p_T > 6 \) GeV/c the data points are comparable with the 200GeV results at all centralities. The \( \pi^0 \) yields in \( Au+Au \) at 39GeV are suppressed in the most central collisions, but no suppression is apparent in more peripheral collisions. At lower energies, a decreasing momentum shift compensates for the steeper slopes at high \( p_T \), making the \( R_{AA} \)’s comparable, in fact, identical in the case of 62.4 and 200GeV. When related to 200GeV, \( n_{\text{eff}}(x_T) \) is similar for 62.4 and 39GeV \( p+p \) and 62.4GeV \( Au+Au \), but very different for the 39GeV \( Au+Au \) data. The new data provided in a wide energy range of \( Au+Au \) collisions will help to constrain energy-loss models.

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions.
