Using the numerical diagonalization method, we investigate the one-dimensional $d$-$p$ model, simulating a Cu-O linear chain with strong Coulomb repulsions. Paying attention to the effect of the transfer energy $t_{pp}$ between the nearest neighbor oxygen-sites, we calculate the critical exponent of correlation functions $K_p$ based on the Luttinger liquid relations and the ground state energy $E_\phi(\phi)$ as a function of an external flux $\phi$. We find that the transfer $t_{pp}$ increases the charge susceptibility and the exponent $K_p$ in cooperation with the repulsion $U_d$ at Cu-site. We also show that anomalous flux quantization occurs for $K_p > 1$. The superconducting region is presented on a phase diagram of $U_d$ vs. $t_{pp}$ plane.

Low-dimensional strongly correlated electron systems attract much interest due to the possible relevance to high-$T_c$ superconductivity. A considerable number of theoretical studies have been performed on the strongly correlated fermion models either in one-band or multi-band version to understand the mechanism of the high temperature superconductivity. However, there is no consensus on what the actual mechanism of the superconductivity is, except for the fact that the strong repulsive interaction on Cu-site plays an important role in the mechanism. To achieve a solid understanding of this problem, some rigorous studies, even of the simplest models, are highly desirable at this stage. For such purpose, numerical diagonalization studies of finite size systems may be successful. In particular, one-dimensional $d$-$p$ model, simulating a Cu-O linear chain with strong Coulomb repulsions, provides a good target to investigate the mechanism of the high-$T_c$ superconductivity. The model contains hopping $t_{pd}$ between Cu(d)-site and oxygen(p)-site and repulsive interaction at the d- and p-site (U_d and U_p, respectively). In addition, it can contain the nearest-neighbor d-p interaction $U_{pd}$ and/or hopping $t_{pp}$ between the nearest-neighbor p-sites.

In the previous work, the present authors have studied the one-dimensional $d$-$p$ model with large on-site Coulomb repulsion $U_d$ at Cu-sites and inter-site repulsion $U_{pd}$, by using the numerical diagonalization method. With the help of the Luttinger liquid relations, the superconducting(SC) correlation is found to be dominant compared with the CDW and SDW correlations in the proximity of the phase separation. The SC phase appears for $1.0 \lesssim U_{pd} \lesssim 1.6$ almost independent of the filling with $1.3 \lesssim n \lesssim 1.7$. Near the half-filling $n = 1$ and the full-filling $n = 2$, however, the SC correlation is suppressed. Recently, Sudbø et al. showed that the $d$-$p$ chain with large $U_{pd}$ exhibits flux quantization with charge $2e$ and slow algebraic decay of the singlet SC correlation function on oxygen sites. Other studies of the $d$-$p$ chain also showed that $U_{pd}$ enhances the charge fluctuation as well as the SC fluctuations and when it exceeds a certain critical value the system becomes unstable towards phase separation. All of these studies claimed that the parameter $U_{pd}$ is central in inducing a SC state at $T = 0$.

However, if one adds the hopping term $t_{pp}$ to the model, the situation will be changed completely. It enhances the charge fluctuation and increases the exponent $K_p$ as the parameter $U_{pd}$ does. Thereafter, the repulsive interaction $U_{pd}$ is not always necessary for the SC state. In the present paper, to clarify the effect of $t_{pp}$, we study the one-dimensional $d$-$p$ model with the hopping $t_{pp}$ by the numerical diagonalization. We calculate the critical exponent of correlation functions $K_p$ and the ground state energy $E_\phi(\phi)$ as a function of an external flux $\phi$. Using the results for the critical exponent, we show a SC region on the $U_d - t_{pp}$ plane.

We consider the following model Hamiltonian for the Cu-O chain:

$$H = t_{pd} \sum_{<ij>,\sigma} (p_{i\sigma}^d d_{j\sigma} + h.c.) + t_{pp} \sum_{<ij>,\sigma} (p_{i\sigma}^d p_{j\sigma} + h.c.) + \epsilon_d \sum_{j,\sigma} d_{j\sigma}^d d_{j\sigma} + \epsilon_p \sum_{j,\sigma} p_{j\sigma}^d p_{j\sigma} + U_d \sum_{j} n_{d\uparrow} n_{d\downarrow}$$  \hspace{1cm} (1)

where $d_{j\sigma}^d$ and $p_{j\sigma}^d$ stand for creation operators of a hole with spin $\sigma$ in the Cu(d)-orbital at site $j$ and of a hole with spin $\sigma$ in the O(p)-orbital at site $i$ respectively, and $n_{d\sigma} = d_{j\sigma}^d d_{j\sigma}$. Here, $t_{pd}$ stands for the transfer energy between the nearest neighbor d- and p-sites, which will be set to be unity ($t_{pd}=1$) hereafter in the present study. The atomic energy levels of d- and p-orbitals are given by $\epsilon_d$ and $\epsilon_p$, respectively. The charge-transfer energy $\Delta$ is defined as $\Delta = \epsilon_p - \epsilon_d$.

To achieve systematic calculation, we use the periodic boundary condition for $N_h = 4m + 2$ and antiperiodic boundary condition for $N_h = 4m$, where $N_h$ is the total hole number and m is an integer. This choice of the boundary condition removes accidental degeneracy so that the ground state might always be a singlet with zero momentum. The filling $n$ is defined by $n = N_h/N_u$, where $N_u$ is the total number of unit cells (each unit cell contains a d- and a p-orbitals) and the Fermi wave number $k_F$ is given as $k_F = \frac{\pi}{2} n$. 

Superconductivity of the One-Dimensional $d$-$p$ Model with $p$-$p$ transfer

We numerically diagonalize the Hamiltonian up to 12 sites (6 unit cells) using the standard Lanczos algorithm. The chemical potential \( \mu(N_h, N_u) \) is defined by
\[
\mu(N_h, N_u) = \frac{E_0(N_h + 1, N_u) - E_0(N_h - 1, N_u)}{2}, \tag{2}
\]
where \( E_0(N_h, N_u) \) is the total ground state energy of a system with \( N_h \) unit cells and \( N_u \) holes. When the charge gap vanishes in the thermodynamic limit, the uniform charge susceptibility \( \chi_c \) is obtained from
\[
\chi_c(N_h, N_u) = \frac{2/N_u}{\mu(N_h + 1, N_u) - \mu(N_h - 1, N_u)} \tag{3}
\]

In the Luttinger liquid theory, some relations have been established as universal relations in the one-dimensional models. \[13\] In the model which is isotropic in spin space, the critical exponents of various types of correlation functions are determined by a single parameter \( K_\rho \), which is the exponent of the power-law decay of correlation functions. For the one-dimensional \( d-p \) model in the weak coupling regime, Matsunami and Kimura \[20\] calculated the critical exponents of some correlation functions by using the renormalization group analysis (g-ology), and shown that the system belongs to the Tomonaga-Luttinger (TL) liquid. In the present authors' recent work, \[8\] we have shown the numerical results of the critical exponent \( K_\rho \) and the phase diagram on the \( U_d-U_{pd} \) plane including the weak coupling region and the strong coupling region. In the weak coupling region, it agrees with the results of the g-ology. An analysis of spin-gap indicates that the strong coupling region also belongs to the TL regime and not to the Luther-Emery (LE) regime. Here, the LE regime is characterized by a gap of the spin excitation spectrum, while in the TL regime, the excitation is gapless. \[14\] \[18\]

It is predicted that SC correlation is dominant for \( K_\rho > 1 \) (the correlation function decays as \( r^{-(1+\frac{1}{\nu_1})} \) in the TL regime and as \( r^{-(1+\frac{1}{\nu_2})} \) in the LE regime), whereas Charge Density Wave (CDW) or Spin Density Wave (SDW) correlation functions decay in the TL regime and as \( r^{-\frac{1}{\nu}} \) in the LE regime. In the TL regime, the singlet SC and triplet SC correlation functions have the same critical exponent apart from a logarithmic correction. On the other hand, in the LE regime, the correlation functions of SDW and triplet SC decrease exponentially. The parameter \( K_\rho \) is related to the charge susceptibility \( \chi_c \) and the charge velocity \( v_c \) by the relations, \[14\] \[17\] \[19\]
\[
K_\rho = \frac{\pi}{2} v_c \chi_c \tag{4}
\]
with \( v_c = \frac{N}{2t}(E_1 - E_0) \), where \( E_1 - E_0 \) is the lowest charge excitation energy. We can also determine the \( K_\rho \) by the Drude weight \( D \)
\[
K_\rho = \frac{1}{2} (\pi \chi_c D)^{1/2} \tag{5}
\]
with \( D = \frac{N}{\pi c} \frac{\partial^2 E(\phi)}{\partial \phi^2} \), where \( E(\phi) \) is the total energy of the ground state as a function of flux \( \phi \). \[14\] Using these two independent equations of the \( K_\rho \), we will check the consistency of the Luttinger liquid relations.

For a non-interacting system (\( U_d = 0 \)), the Hamiltonian (1) is easily diagonalized and a dispersion relation is given as
\[
E(\pm)(k) = \frac{1}{2} \left\{ \epsilon_d + \epsilon_p + 2t_{pp} \cos k \pm \sqrt{[(\Delta + 2t_{pp} \cos k)^2 + 16(t_{pd} \cos (k/2))^2]} \right\} \tag{6}
\]
where \( k \) is a wave vector and \( E^+(k)(E^-(k)) \) represents a upper (lower) band energy. Compared with the case with \( t_{pp} = 0 \), the width of the lower band \( E^-(k) \) becomes narrower for \( t_{pp} > 0 \). Note that it decreases with \( \Delta \) and becomes perfectly flat at \( \Delta = 2t_{pp} - t_{pd}^2/t_{pp} \). When one decreases \( \Delta \) further, the band bends with a peak at \( k = 0 \). To investigate the band structure of interacting systems, we consider the chemical potential \( \mu \), which is corresponding to Fermi energy \( E_F \) at \( T = 0 \). Figure 1(a) shows \( \mu \) as a function of the filling \( n \) for several values of \( U_d \) with \( \Delta = 2 \) and \( t_{pp} = 0.5 \). We calculate the value of \( \mu \) by using eq.2 at the hole densities \( n = \frac{5}{4}, \frac{7}{4}, \frac{5}{2}, \frac{7}{5}, \frac{9}{5}, \frac{7}{6}, \frac{9}{6} \) and \( \frac{11}{6} \). Data points with \( U_d = 0 \) seem to sit closely along on the dispersion curve of \( E^-(k_F) \). It suggests that the finite-size effect is sufficiently small.

When \( U_d \) is large, \( \mu \) is large and weekly depends on \( n \). Especially, the slope of \( \mu \) becomes almost flat at \( U_d = 6.5 \). In this case, the charge susceptibility \( \chi_c \) almost diverges, because of the relation, \( \chi_c^{-1} = \frac{4\pi}{\mu} \). The result suggests that the width of effective hole band becomes very narrow due to a strong correlation effect of large repulsion \( U_d \). In order to see the behavior of the charge susceptibility more qualitatively, in Fig. 1(b), we show the inverse of the charge susceptibility \( \chi_c^{-1} \) as a function of \( U_d \) in a system with 6 unit cells for \( \Delta = 2 \). In the case of \( t_{pp} = 0 \), the \( U_d \)-dependence of \( \chi_c^{-1} \) is weak and \( \chi_c^{-1} \) remains as a finite value. On the other hand, it is close to zero at \( U_d \simeq 6.75 \) for \( t_{pp} = 0.5 \). It shows that the transfer \( t_{pp} \) increases the charge susceptibility in cooperation with the repulsion \( U_d \). If we use the Hartree-Fock(H.F.) approximation, the atomic levels of \( d \)-orbitals \( \epsilon_d \) are pushed up as \( \epsilon_d = \epsilon_d + \frac{U_d}{2} < n_d > \), where \( < n_d > \) is the mean value of hole density \( n_d \) at a \( d \)-site and determined by solving the self-consistent equation of \( < n_d > \). Then, the band structure is approximately described as a renormalized band \( \tilde{E}^{-}(k) \) whose \( \Delta \) is replaced by \( \tilde{\Delta} = \Delta - \frac{1}{2}U_d < n_d > \). The band width of \( \tilde{E}^{-}(k) \) decreases as \( \tilde{\Delta} \) decreases and becomes zero at sufficiently large \( U_d \). The decreases of the band width leads to the enhancement of \( \chi_c \) as shown in Fig.1(b).
Next, we show the critical exponent of correlation functions $K_\rho$ as a function of $U_d$ in Fig.2(a). We calculate $K_\rho$ in two ways by using eq.(4) and eq.(5) independently, one is obtained by combining the charge velocity $v_c$ and the charge susceptibility $\chi_c$ and the other is expressed by the Drude weight. The result shows that the values of $K_\rho$ obtained by in the two different ways are well consistent with each other except for $U_d \lesssim -1$. We also show $K_\rho$ obtained by the g-ology together in Fig.2(a). In the weak coupling regime, the results of numerical diagonalization are in good agreement with those of the g-ology. These results indicate that the Luttinger liquid theory can be applied to the one-dimensional $d$-$p$ model successfully and finite-size effect of $K_\rho$ is not so large.

To judge which of the two estimations of $K_\rho$ is better from a point of view of finite-size effect, we watch the values of $K_\rho$ at $U_d = 0$. The one from eq.(4) is equal to 0.972 and the other from eq.(5) is 1.002. Taking account of $K_\rho$ being always equal to unity in noninteracting case, we infer that the estimation from eq.(5) is better than the other. Furthermore, the comparison of those values of $K_\rho$ with the values obtained in the g-ology in the weak coupling regime also indicates that the estimation of $K_\rho$ from eq.(5) gives a better result. Therefore, we will use the value of $K_\rho$ expressed by eq.(5) in the following.

Fig.2(a) shows that $K_\rho$ decreases as $U_d$ increases when $U_d \lesssim 3$. However, $K_\rho$ increases with $U_d$ for $U_d \gtrsim 3$ and diverges at $U_d \sim 6.8$ where the charge susceptibility diverges. The divergence indicates that the width of the effective band $E^-(k)$ is close to zero. When $K_\rho$ is larger than unity, the SC correlation is expected to be most dominant compared with CDW and SDW correlations. The region where $K_\rho > 1$ appears at $6.5 \lesssim U_d \lesssim 6.8$. It seems to be fairly small, but surely exists. To confirm the ground state to be in the SC state, we show the ground state energy $E_0(\phi)$ as a function of an external flux $\phi$ in Fig.2(b). The anomalous flux quantization occurs at $U_d = 6.7$, where $K_\rho$ is about 2.0. When $U_d = 6.0$, $K_\rho$ is less than unity and the anomalous flux quantization is not found. These results support that the SC phase really appears at $K_\rho > 1$.

Generally speaking, the SC phase is induced by an attractive interaction between quasi-particles. To examine the effective attraction, we introduce the repulsive interactions $U_{dd}$ ($U_{pp}$) between the nearest-neighbor $d$-$d$ ($p$-$p$) sites and the repulsion $U_p$. If those repulsions act between a relevant pair of holes or cancel the effective attraction, the SC state is expected to be suppressed and $K_\rho$ is reduced. We find that $U_{dd}$ does not affect $K_\rho$, but $U_p$ ($\gtrsim 0.2$), as well as $U_{pp}$, decreases it. It suggests that the relevant pair of holes sit not on the $d$-sites but on the $p$-sites and the strength of the attraction is of order of 0.2. [2]
and promotes the SC correlation as $U$ have confirmed that region where the renormalized band becomes flat. We and SDW correlations in the proximity of the parameter $K$ of $\rho$ parameter plane. Figure 3 shows a contour map of $\rho$ for $\Delta = 8/5$ system. The region sandwiched between two lines with $K = 1$ and $K = \infty$ is corresponding to the SC region. The region is very small for small $U$, however, it increases with $U$.

In the H.F. approximation, the renormalized band $E^c(k)$ becomes flat at a critical value $t_{pp}'$ which is given as

$$t_{pp}' = \frac{1}{4} \left\{ \Delta - \frac{1}{2} U_d < n_d > + \sqrt{\left( \Delta - \frac{1}{2} U_d < n_d > \right)^2 + 8 t_{pd}^2} \right\}. $$

Here, the approximation breaks down for $t_{pp} \geq t_{pp}'$. We expect that the point of $t_{pp} = t_{pp}'$ corresponds to that of $K = \infty$. In the noninteracting system $(U_d = 0)$, $t_{pp}' = \frac{1-\sqrt{\Delta}}{2}$ for $\Delta = 2$. As $U_d$ increases, $t_{pp}'$ decreases as shown in Fig.3. It seems that the line of $t_{pp}'$ is near that of $K = \infty$.

In summary, we have numerically diagonalized the one-dimensional $d$-$p$ model with finite sizes. Paying special attention to the role of $t_{pp}$, we have calculated chemical potential and critical exponent $K$. We have also showed the anomalous flux quantization observed in the SC state. Using the Luttinger liquid relations, we have found that the SC correlation is dominant compared with the CDW and SDW correlations in the proximity of the parameter region where the renormalized band becomes flat. We have confirmed that $t_{pp}$ enhances the charge fluctuation and promotes the SC correlation as $U_{pd}$ does.

[21] If we regard the origin of the attraction as the super exchange interaction $J$ acting between the nearest-neighbor Cu-spins, its order seems to be consistent with the strength of the effective attraction. Here, the exchange energy is given as $J \approx \frac{2}{\Delta d} \left[ \frac{1}{U_d} + \frac{1}{2 \Delta U_d} \right]$, which is estimated to be $J \approx 0.3$ with $\Delta U_d = 1$, $\Delta = 2$, $U_p = 0$, and $U_d = 6.5$.
